R0	September 21, 2023	Initial release
R1	October 31, 2023	Revised for NWMO comments

TABLE OF CONTENTS

1	INTRODUCTION	1
1.1	Borehole SB_BH02.....	1
1.2	Hydraulic Testing Activities	4
1.3	Reported Analyses.....	4
2	EQUIPMENT	5
2.1	Mobile Integrated Aquifer Testing & Analysis (MIATA) Platform	5
2.2	Data Acquisition and Control System (DACS)	7
2.3	Pressure Maintenance System.....	8
2.4	Hydraulic Test Tool (HTT).....	9
2.4.1	Packers.....	9
2.4.2	Downhole Shut-In Valve.....	10
2.4.3	Sensor Carrier	11
2.4.4	Piston Pulse Generators	11
2.4.5	Test Interval	12
2.4.6	Pressure Transducers.....	13
2.4.7	Temperature Transducers.....	13
2.4.8	Tubing String	13
2.4.9	Barometer.....	14
2.5	Summary of Measurement and Test Equipment	14
3	TESTING METHODOLOGY	17
3.1	Tool Assembly.....	17
3.2	HTT Installation and Leak Testing.....	17
3.3	Packer Inflation	18
3.4	System Stabilization	19
3.5	Slug Testing.....	20
3.6	Pulse Testing.....	20
3.7	Test Termination	20
3.8	Real-Time Analysis	20
4	ANALYSIS APPROACH	22
4.1	Conceptual Model	22
4.2	Parameters.....	23
4.3	Tests.....	24
4.4	Formation Specific Storage - Skin Conductivity - Skin Thickness	25
4.5	Pre-Test Borehole History	27
4.6	Test Zone Thermal Effects.....	28
4.7	Uncertainty Analysis.....	30
5	TEST INTERVALS	37
6	INDIVIDUAL TEST ANALYSES.....	40
7	ANALYSES SUMMARY.....	41

1 INTRODUCTION

Geofirma Engineering Ltd. (Geofirma) was retained by the Nuclear Waste Management Organization (NWMO) to complete a drilling and testing program for two deep bedrock boreholes (SB_BH01 and SB_BH02) as part of the NWMO's Phase 2 Geoscientific Preliminary Field Investigations. The full scope of this deep drilling and testing program is described in the Initial Borehole Characterization Plan.

Phase 1 of NWMO's APM plan included preliminary desktop studies using available geoscientific information and a set of key geoscientific characteristics and factors that can be realistically assessed at the desktop phase of the Preliminary Assessment. The Phase 1 Preliminary Assessment of the South Bruce area identified the Cobourg Formation as the preferred host formation for a deep geological repository for used nuclear fuel. The Initial Borehole Drilling and Testing study is a key component of the Phase 2 Geoscientific Preliminary Field Investigations of the NWMO's APM plan.

The activities described in this report constitute one component of the Geofirma geoscientific investigations as part of the NWMO Phase 2 Initial Borehole Drilling and Testing Program within the South Bruce site, near Teeswater, Ontario (Figure 1.1).

An important component of this geoscientific investigation is the acquisition of in situ estimates of rock mass hydraulic conductivity (K) and other hydrogeologic formation properties including formation pressure (P_f) and specific storage (S_s).

Specifically, this report presents the results of analyses of data collected during hydraulic testing in borehole SB_BH02 as described in Geofirma's WP06 Test Plan. Testing was conducted by subcontractor HydroResolutions LLC (HR) under the direction of senior Geofirma staff.

This report describes the results of the testing and analyses associated with SB_BH02. Figure 1.2 shows the stratigraphic sequence that was encountered in the subsurface while drilling SB_BH02. The subsurface nomenclature used was based on Armstrong and Carter (2010).

1.1 Borehole SB_BH02

Borehole SB_BH02 is located approximately 5.5 km northwest of the community of Teeswater, Ontario, and was drilled to 900.57 m below ground surface (mBGS). SB_BH02 was drilled through the entire sedimentary bedrock sequence to approximately 14 m into the Precambrian basement. SB_BH02 is located approximately 2.5 km west of SB_BH01. The borehole was drilled using PQ3 wireline coring equipment that produces a 123 mm nominal diameter borehole and 83 mm nominal diameter core over the period August 19, 2021 until March 22, 2022 using brine as a drilling fluid. Borehole geophysical logging was completed over the period April 15, 2022 until June 1, 2022.

Notes:

a - Strata traditionally referred to as Middle Ordovician (i.e., Black River and Trenton groups; Armstrong and Carter, 2006) are now considered Part of the Upper Ordovician.

b - The formal term Middle Silurian (e.g., Armstrong and Carter, 2006) has been abandoned so all strata have been re-assigned to either the Lower or Upper Silurian.

c - A0 Unit (Salina Formation) is recognized based on site characterization activities at the Bruce nuclear site (Intera, 2011).

d - Unit/Formation is not expected but may be present.

Surface Nomenclature Equivalent (approx.): 1 - Lindsay Fm; 2 - Verulam Fm; 3 - Bobcaygeon Fm

----- Unconformity

1.2 Hydraulic Testing Activities

Straddle-packer hydraulic testing of South Bruce borehole SB_BH02 provided the data required to determine in situ values of hydrogeologic properties. A custom test tool and support trailer with a data-acquisition system was developed to address the unique requirements of low-permeability testing in deep boreholes. The test equipment was designed and constructed by HR staff and drew upon years of experience in testing of low-permeability strata at multiple locations around the globe.

The key components of the test tool are: two inflatable packers to isolate a test interval within a borehole; a downhole shut-in valve that connects or isolates the test interval from the tubing on which the test tool is suspended in the hole; a hydraulic piston that can be extended or retracted to cause a pressure increase or decrease in the test interval; and pressure transducers that measure the pressure in the test interval, in the bottom of the hole below the lower packer, in the tubing string above the test tool, and in the annulus between the tubing and borehole wall above the upper packer.

SB_BH02 testing was carried out between June 5, 2022, and August 24, 2022, in fifteen 29.96-m intervals and five 5.03-m intervals. These tests were performed under control of WP06 Test Plan.

1.3 Reported Analyses

This report summarizes the analyses of straddle-packer hydraulic testing performed in borehole SB_BH02. This testing included fourteen pulse tests and one slug test in the 29.96-m intervals and three pulse tests and two slug tests in the 5.03-m intervals.

Transient pressure data collected during straddle-packer hydraulic testing were analyzed using version 3.00T of the nSIGHTS (**n**-dimensional **S**tatistical Inverse **G**raphical **H**ydraulic Test **S**imulator) well-test-analysis software, a numerical well-test analysis code written in C++ and described in detail in the nSIGHTS User Manual (Geofirma and INTERA, 2011).

2 EQUIPMENT

Low-permeability testing is subject to non-ideal testing conditions that can have significant impact on testing results and suitability of results for analysis. The uncertainty associated with these conditions was minimized through effective equipment design for the SB_BH02 testing.

Most tests performed in the SB_BH02 borehole were pulse tests. The pressure response observed during a pulse test is directly proportional to the wellbore storage coefficient of the test interval. The wellbore storage coefficient has two components: the volume of fluid contained within the test zone (V_{tz}) and the compressibility of all the materials within or in contact with the test zone (C_{tz}). V_{tz} includes the volume of fluid between the packers, within any tubing or equipment components below the shut-in valve, and within the feedthrough line connected to the test-zone transducer. C_{tz} is a composite compressibility that includes contributions from the test equipment, the borehole fluid, and the geomechanical response of the borehole wall. To minimize the time required to complete a pulse test, the SB_BH02 equipment was carefully designed and selected to minimize both V_{tz} and C_{tz} . During the SB_BH02 borehole testing, V_{tz} was approximately 0.44 m³ for 29.96-m test intervals and approximately 0.085 m³ for 5.03-m test intervals. C_{tz} was minimized through use of extremely stiff packers with high inflation pressures and strong interconnecting components. Most tool feedthroughs and connections were custom-machined stainless-steel components.

During pulse tests in low-permeability formations, variations in packer pressures can cause perceptible changes in test-zone pressure that can mask the actual formation response. To minimize variations in packer pressures, a pressure maintenance system (PMS, see Section 2.3) was hydraulically connected to the packers during testing. The PMS was also connected to the shut-in valve and the pulse piston hydraulics.

Another important equipment design feature was to provide remote access to the test data in real time. This allowed for off-site supervision of testing and for continuous monitoring of the test response. Remote access also allowed for near real-time preliminary test analyses.

The testing equipment consisted of downhole and surface components. The downhole equipment was connected to surface with four stainless steel hydraulic lines (packer inflate/deflate, piston extend, piston retract, shut-in valve close) and an umbilical cable with transducer power and communication lines. The hydraulic lines and umbilical cable were clamped to the outside of a 2-3/8 inch tubing string that provided the overall mechanical connection between the service rig at surface and the downhole tool.

2.1 Mobile Integrated Aquifer Testing & Analysis (MIATA) Platform

The MIATA platform is a testing system developed by HR and provided capabilities for conducting the SB_BH02 hydraulic tests through a wide range of weather conditions. The MIATA platform provided a controlled environment from which personnel conducted the on-site operations required to successfully execute the hydraulic testing program. The MIATA platform protected all above-ground instrumentation and equipment from exposure to the weather and animals.

The MIATA platform was designed and developed to accommodate both low-permeability and conventional hydraulic testing activities. The operation of the hydraulic test tool (HTT) for low-

permeability hydraulic testing applications was one of its core capabilities. The MIATA platform design included:

- Internal hydraulic line control through a pressure manifold;
- Pressure maintenance system to minimize temperature-dependent pressure fluctuations in the packers and downhole hydraulic lines;
- Custom data acquisition and control system (DACS).

Figure 2.1 and Figure 2.2 show the exterior and interior of the MIATA platform, respectively.

Figure 2.1 MIATA platform (white trailer) at the SB_BH01 testing site. A similar configuration was used at SB_BH02.

Figure 2.2 Interior of MIATA platform.

2.2 Data Acquisition and Control System (DACS)

The DACS allowed for the collection of data associated with the hydraulic testing and for secure off-site remote access via the internet. This capability reduced the number of on-site personnel required by allowing real-time analysis of the hydraulic tests to be conducted remotely. This also allowed designated parties real-time access to the data and the ability to provide input to the hydraulic testing process as it took place.

The DACS consisted of a remote terminal unit (RTU) connected via ethernet to a field laptop running a real-time monitoring and control system (RTMCS). The RTU received digital and analog measurements from the sensors, converted the analog measurements to engineering units, and recorded the measurements with date-time timestamps to an ASCII file in internal memory using a time interval set by the operator. A file server then automatically transferred the data to the field laptop. If the connection to the field laptop was lost, the RTU continued to record the data until a connection was re-established, at which time it transferred all the buffered data to the field laptop where it was stored in a OneDrive directory accessible by remote staff. The RTMCS provided graphic and numeric read outs of the measurements and allowed the operator to set the recording interval. The RTMCS also maintained an independent database of the measurements, read directly from the RTU, and recorded with a 10-second interval.

2.3 Pressure Maintenance System

The pressure maintenance system (PMS) was a critical component in successfully conducting high quality hydraulic tests in very low-permeability systems. Diurnal temperature changes on the surface cause the expansion/contraction of fluid in the packer inflation lines. In low-permeability intervals, even small variations in packer pressure directly affect the pressure response in the test zone. The PMS virtually eliminated the pressure fluctuations, resulting in a much cleaner pressure response in the test zone.

The PMS had three principal components:

- A pressurised nitrogen source (bottle) with pressure regulator,
- An Alicat pressure controller, and
- A high-pressure hydraulic accumulator containing pressurised nitrogen in a bladder over packer-inflation fluid.

The Alicat pressure controller is connected to the nitrogen bottle and to the accumulator (see schematic diagram in Figure 2.3). The desired packer-inflation pressure (“set” point) is entered into the controller, which has an integral pressure sensor. The controller then adds nitrogen to the accumulator if the pressure drops below the set point or vents nitrogen from the accumulator if the pressure rises above the set point.

Figure 2.3 Schematic of Packer Pressure Maintenance System.

2.4 Hydraulic Test Tool (HTT)

The straddle-packer HTT (Figure 2.4) consisted of two inflatable packers, a downhole shut-in valve (DHSIV), a piston-pulse generator (PPG), a sensor (or Gauge) carrier, a perforated section, and miscellaneous subs and pass-throughs to connect the various pieces and minimize the fluid volume in the test zone.

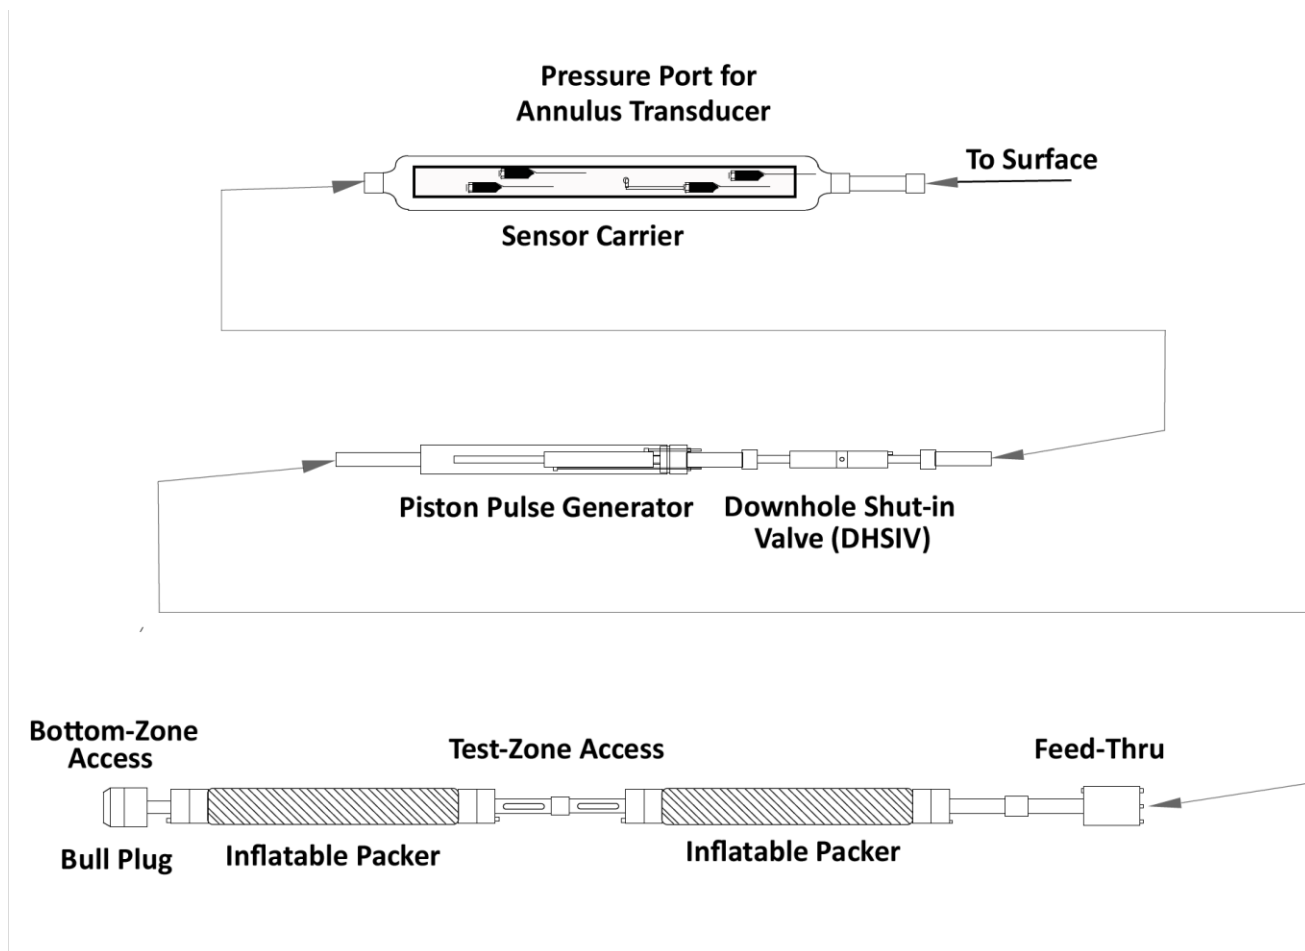

Figure 2.4 General Hydraulic Test Tool Schematic.

2.4.1 Packers

Baski 4.1-inch (104 mm) external-inflate sliding-end Fracker packers (Figure 2.5) were used in the HTT for testing in the PQ (123 mm) borehole. The packers had an uninflated diameter of 104 mm and an element length of 1.14 m, which provided a seal length of approximately 1.0 m in a 123-mm-diameter hole. The packers were capable of withstanding differential pressures of up to 20.7 MPa (3000 psi). The packers and packer-inflation line were filled with non-toxic antifreeze with a density less than 1 gm/cm³ and inflated using a single ¼-inch stainless steel line by pressurizing a fluid reservoir at the surface with compressed nitrogen to 5 to 15 MPa (725 to 2175 psi), depending upon depth and formation properties. Actual packer inflation pressure depended upon interval depth. The packers were placed on the pressure maintenance system (PMS) once inflated to the desired initial pressure. The packers

were oriented so that their fixed ends were up and their sliding ends were down, to avoid putting inflation lines in tension and so that the packers didn't compress and expand during HTT removal.

Some element of abrasion protection for the packers was provided by the largest diameter (115 mm) components in the system, which were the bull plug below the bottom packer and the feedthrough above the top packer.

Figure 2.5 Baski Fracker Packer.

2.4.2 Downhole Shut-In Valve

A downhole shut-in valve (DHSIV) (Figure 2.6) was used to control the connection between the interior of the tubing string above the HTT and the test zone between the inflatable packers. The DHSIV was manufactured by Inflatable Packers International Pty. Ltd. (IPI) of Australia and used a piston-actuated ball valve within a stainless steel housing. The valve was set up in a normally open position and hydraulic pressure was applied to push an annular piston down, rotating the ball 90° to close the valve. A spring pushed the piston up, opening the valve, when the hydraulic pressure was relieved. The ball had a 1.27-cm-diameter opening and caused no displacement in the test interval when it was actuated. A single ¼ inch stainless steel line was used for DHSIV actuation. As for the packers, a lighter-than water non-toxic antifreeze (plumber's antifreeze) was used as the hydraulic fluid for operation of the DHSIV.

Figure 2.6 Downhole Shut-In Valve (DHSIV).

2.4.3 Sensor Carrier

The transducers (Section 2.4.6) used to monitor pressures were mounted in a sensor carrier that was located at the top of the HTT and enclosed and protected the transducers in the borehole.

2.4.4 Piston Pulse Generators

For pulse-testing applications, a pressure pulse was created by displacing a known volume of fluid in the test zone using a hydraulically actuated piston (Figure 2.7). Four versions of the PPG were available with displacement volumes of 15, 30, 60, and 100 cm³ so that several hundred kPa pulses could be produced in test intervals with different volumes. For the SB_BH02 pulse tests, the 15 cm³ piston was used in all the 5.03-m intervals and the 100 cm³ piston was used in all the 29.96-m intervals. The hydraulically actuated pistons were located inside a custom housing that resided above the top packer (but was hydraulically connected to the test zone). The PPG was extended/retracted using two ¼ inch stainless steel hydraulic lines.

Figure 2.7 Hydraulic Pulse Generating Piston.

2.4.5 Test Interval

Two sections of the tool string between the straddle packers allowed flow from the straddled test zone into the tool string. Two perforated 1-ft (0.3048 m) long pup joints of 2-inch NUE stainless steel pipe were used for this purpose. The pup joints (Figure 2.8) had a total of 10,000 mm² (15 in²) open area available to flow into the HTT.

In addition to the perforated sections, two nominal 10m tubing joints and 6 pup joints were used to create the 29.96 m test zone interval. In SB_BH01 the test interval was 30.05 m. However, one of the pup joints in SB_BH01 was damaged during tool disassembly at the completion of testing and replaced with a shorter joint, resulting in a 9 cm reduction in test zone length. The 5.03 m test zone interval was created with 2 pup joints and is the same size as the short SB_BH01 interval.

Figure 2.8 Perforated Pup Joints.

2.4.6 Pressure Transducers

For both the 29.96-m and 5.03-m straddle-packer tool configuration, four Keller PAA-33X 30 MPa (300 bar) pressure transducers were used to monitor pressure in the zone below the bottom packer (BZ), the zone in between the packers (TZ), the zone above the top packer between the tubing and borehole wall above the upper packer (Annulus), and inside the tubing string (Tubing). The transducers were housed in a sensor carrier (described above) positioned above the shut-in valve. The transducers had internal electronics that produce temperature-compensated floating point values that were transmitted as text to the data acquisition and control system (DACS) via RS485 Modbus serial data link. The Keller transducers were factory calibrated by Keller, Inc., in May 2020. A second calibration was performed at the conclusion of SB_BH01 testing (Table 2.1) and prior to the start of SB_BH02 testing.

The packer pressures, shut-in valve pressure, and piston pressures were monitored with Omegadyne pressure transducers with an operating range of 0-3000 psia (~0-20.7 MPaa). The Omegadyne transducers had a 4-20 mA output which was monitored by the DACS and converted to pressure in engineering units (psi). Hydraulic pressures are not quality-affecting data; the primary purpose of monitoring pressures is to verify that the packers have inflated and to keep their pressure constant.

2.4.7 Temperature Transducers

HOBO temperature logging transducers were installed in the test zone and bottom zone by taping the transducers to the tool below the top and bottom packers.

2.4.8 Tubing String

The test tool was raised and lowered in the borehole using a tubing string comprised of nominally 28 to 32 ft (8.5 to 9.8 m) long joints of 2-3/8" diameter EUE tubing, rated for pressures in excess of 75 MPa.

The 2-3/8" EUE tubing string threaded directly into the top of the sensor carrier. Shorter lengths of tubing (pup joints) were used for adjustment of the tool depth, allowing the open end of the tubing to be a reasonable length above the rig deck (nominally 1 m). All pup joints were measured and included in the recorded tubing tally.

2.4.9 Barometer

Barometric pressure was monitored during all hydraulic tests using an In-Situ BaroTroll with a useable pressure range of 16.5 psi (113.7 kPa). The BaroTroll has internal electronics that produce temperature-compensated floating point values that are transmitted to the DACS via RS485 Modbus.

2.5 Summary of Measurement and Test Equipment

Measurement and test equipment (M&TE) requiring calibration, and calibration status are listed in Table 2.1. With the exception of the Alicat and BaroTroll transducers, calibration dates listed in the table are for the post-calibration conducted at the completion of SB_BH01 testing.

Table 2.1 Measurement and Test Equipment Calibration Summary.

ID	Description	Serial #	Calibration Date	Calibration Renewal Date
Keller-1	TZ transducer	1096425	26 May 2022	26 May 2023
Keller-2	BZ transducer	1096424	26 May 2022	26 May 2023

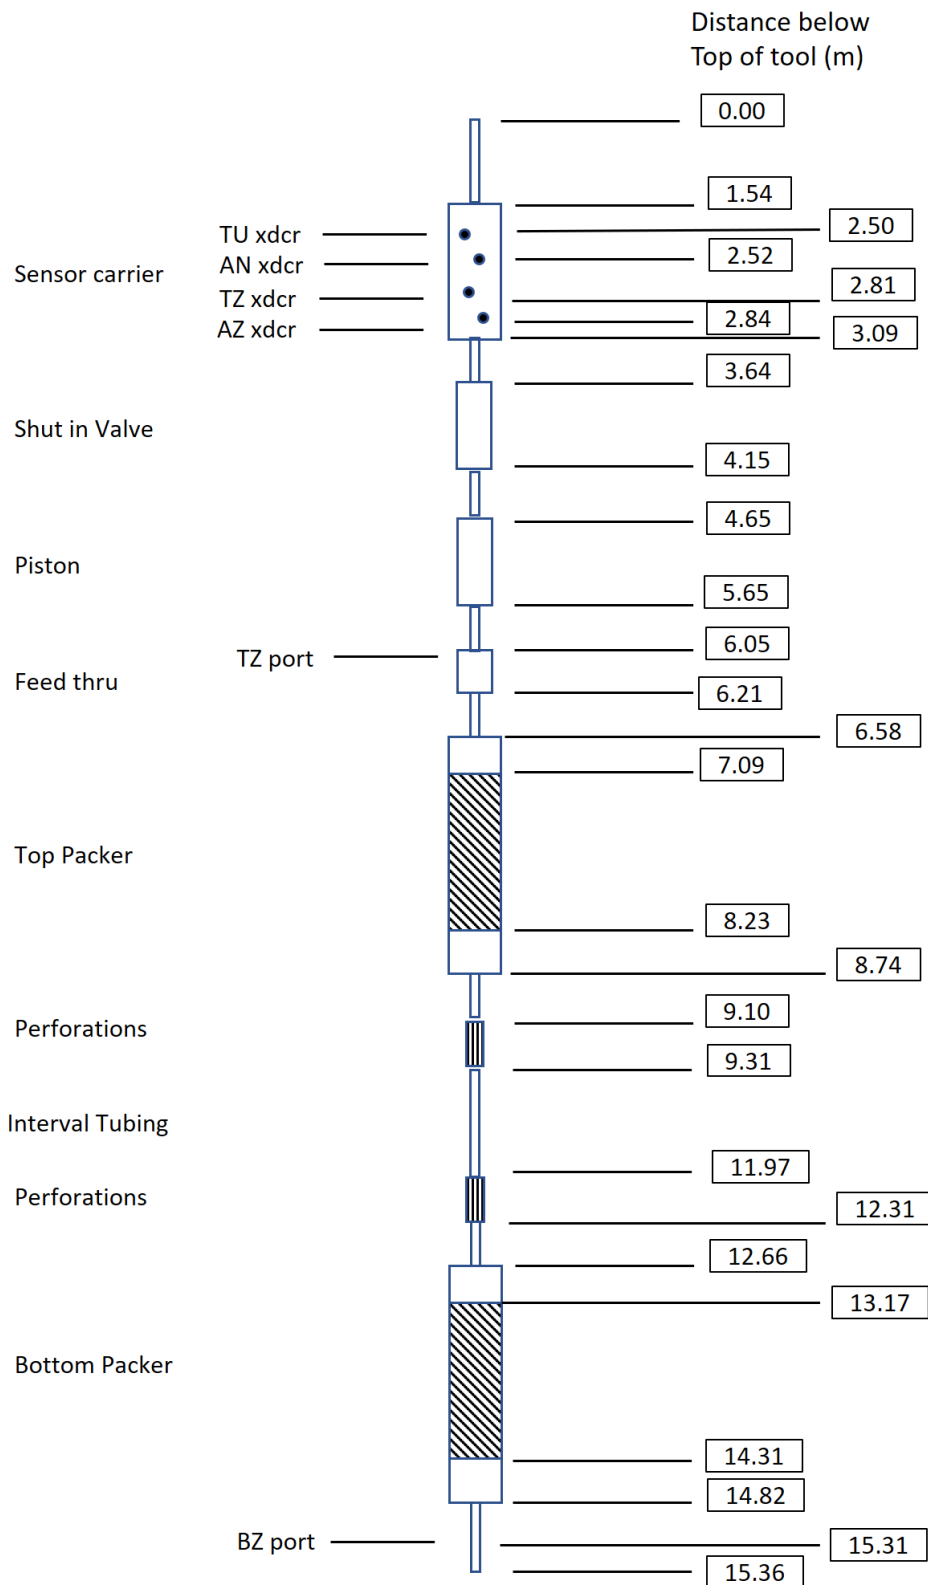

Figure 2.10 As-built 5.03-m test tool with measurements.

3 TESTING METHODOLOGY

3.1 Tool Assembly

The HTT was too long to be completely assembled at surface and then lowered in the hole. Consequently, the tool was assembled in sections (top of tool to upper packer, interval joints, lower packer and below) on surface with the individual sections assembled over the borehole. Hydraulic lines and fittings were pressure tested and “snooped” as the tool was assembled. “Snooping” involves squirting soapy water over the connection and visually monitoring for bubbles.

3.2 HTT Installation and Leak Testing

The HTT was lowered into the well on 2-3/8 inch tubing, with the shut-in valve open, to its desired position with respect to the first interval to be tested. Tubing joints were prepared with PTFE thread sealant and assembled with pipe wrenches to ensure a leak proof seal. For subsequent intervals, the tool was moved down to the specified interval position.

Leak testing in the surface casing was performed before the test tool was lowered to formation depths. The tool was typically lowered to a depth of 40 metres below the static water level in the BH. Packers were inflated with the DHSIV open and the pulse piston in retracted position. After inflation, the DHSIV was closed and the pressure monitored for fluctuations that indicate fluid leakage into the TZ. The pulse piston was extended producing a pulse, and the response monitored for several hours. The leak tests were analyzed in nSIGHTS to ensure the apparent hydraulic conductivity met the criterion of less than 10^{-13} m/s. Leak testing was also performed after each tool reconfiguration or repair during testing. All accepted leak tests were significantly tighter than the acceptance criterion, with apparent hydraulic conductivities down to 10^{-15} m/s. Results for initial leak testing on the 5 m tool configuration are shown in Figure 3.1.

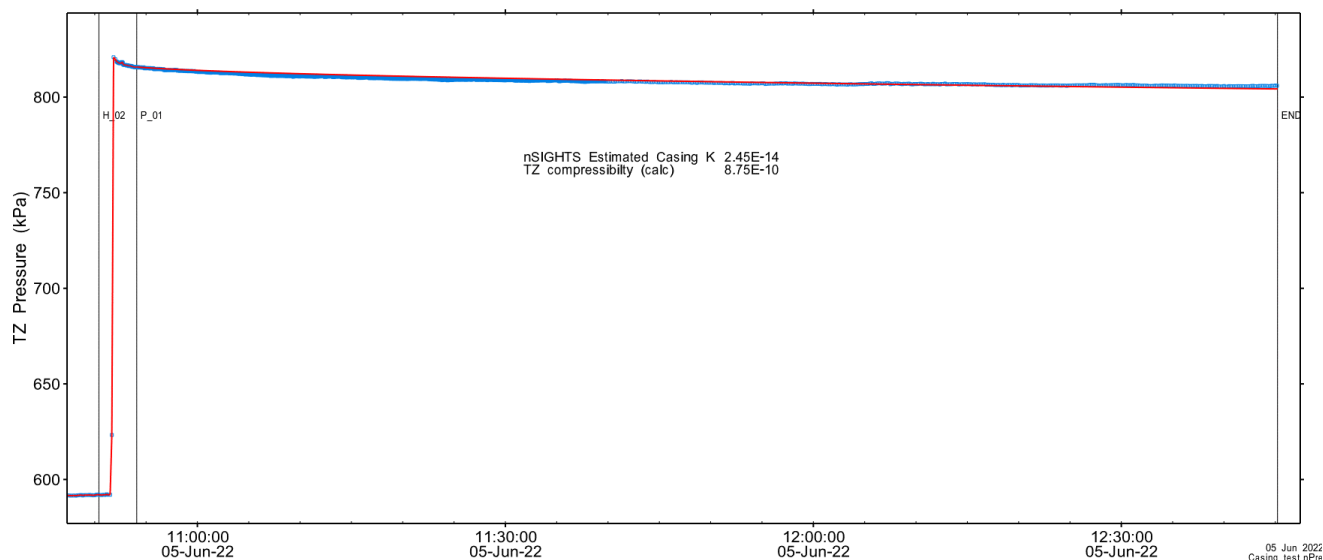

Figure 3.1 Analysis of leak test of 5.03 m HTT system.

Based on the target depth and tool measurements, the number of full joints of tubing needed for the HTT installation was calculated. Additional tubing joints and/or pup joints were added as needed to position the HTT precisely. In selecting and positioning pup joints, allowance was made for handling requirements at the surface. All tubing tallies and depth calculations were verified by a second individual and recorded before testing of an interval began. Tubing and pup joint calculations were recorded in the DQCW tubing tally sheet for each test.

Communication with the downhole pressure transducers was verified after every 10 joints (approximately 100 m) of tubing was installed.

Once the HTT was positioned at the desired depth, all transducers were connected to the DACS and data acquisition was initiated. The water levels in the annulus and the tubing string were measured at this time. The heights of the water columns in the tubing and annulus above the tubing and annulus transducer ports, respectively, combined with coincident pressure measurements allowed for two calculations of the effective water density, serving as a cross-check. All data relevant to these calculations and the calculation results were recorded in the DQCW. If calculated densities were significantly different, water level measurements were rechecked until reasonable agreement was established.

After all planned 5-m test intervals were completed, the HTT was tripped out of the borehole and a final leak test performed prior to reconfiguring the HTT for the 30-m testing.

3.3 Packer Inflation

Minimizing test-zone compressibility (C_{tz}) is imperative to maximize pulse test pressure response in low-permeability intervals. The most significant factor in test-zone compressibility is packer inflation pressure. Packers were inflated to the maximum pressure possible without impacting formation integrity and consistent with operational constraints. A geo-mechanical analysis of formation breakdown pressures (Figure 3.2) calculated maximum packer inflation system pressures at surface as a function of test interval depth. Formation breakdown pressure is an estimate of the radial pressure at which fracturing of the adjacent formation may occur. Combining the maximum calculated pressure with an operating pressure range (minimum required to inflate packers and maximum safe operating pressure of MIATA components) yielded a linearly varying range of maximum packer inflation from 6 MPa at 200 mBGS to 15 MPa below 560 mBGS.

Excessive N_2 consumption by the Alicat controller during testing required a reduction of maximum pressure to 11.7 MPa (1700 psi) which was used for all tests deeper than 430 mBGS. Calculated test zone compressibility was close to estimated borehole fluid compressibility for nearly all tests.

Packers were inflated to the desired pressures and PMS settings were recorded. The shut-in valve was maintained in an open position while the packers were inflated to avoid pressure squeeze in the test interval.

Figure 3.2 Packer Inflation Pressure Ranges

3.4 System Stabilization

Hydraulic pressures were reviewed to ensure the pulse piston position was “retracted” for testing to begin with a pulse injection.

After the pulse piston position was confirmed, the DHSIV was closed. Piston position and DHSIV closing time were recorded. The pressure in the now isolated test zone then began to change relative to the annulus pressure and the tubing pressure, as the test-zone pressure equilibrated with the far-field static pressure of the interval being tested. The bottom hole pressure typically showed a pressure increase during packer inflation due to “packer squeeze,” and then either increased or decreased depending on the natural formation pressure in the interval isolated below the bottom packer. Tubing string pressure remained constant apart from minor effects due to the atmospheric pressure changes once the DHSIV was closed.

Initially, the tubing pressure and annulus pressure were similar. Prior to initiating a slug test, enough water was removed from the tubing to lower the tubing pressure by approximately 150 to 350 kPa.

The system was then typically left to stabilize/equilibrate overnight. The stabilization period was sometimes shortened if relatively stable pressure conditions were obtained rapidly, as was the case in higher permeability test intervals. Note that equilibration did not necessarily mean a constant TZ pressure, as under-pressured or over-pressured formations and/or borehole history sometimes caused TZ pressure to rise and fall, and several hours of equilibration would not compensate for the effects of weeks of pre-test borehole history.

3.5 Slug Testing

After equilibration, the DHSIV was opened in certain intervals to initiate a slug withdrawal and the event was recorded. Slug tests were performed in three SB_BH02 intervals: HT01_05 (Salina A2 Evaporite); HT02_05 (Guelph); and HT03_30 (Goat Island).

3.6 Pulse Testing

After equilibration, pulse-injection tests were initiated in certain intervals by extending the piston. The pulse pressure differential (TZ pressure immediately before and after pulse initiation) was used along with the test-zone volume and pulse-piston displacement volume to calculate the test-zone compressibility (C_{tz}). Test-specific C_{tz} is an essential parameter for accurate simulation of pulse tests. C_{tz} integrates the essential components of the combined test tool, test zone and formation mechanical response. When combined with the actual test zone fluid volume, it forms the boundary condition term for pulse tests. It is not possible to accurately estimate C_{tz} without either a PPG or accurate measurements of tubing string fluid level changes in response to the DHSIV open/close sequences. Test-specific variables such as packer construction details, packer inflation pressure, formation rock compressibility, and test zone fluid compressibility preclude using estimated or generic values. Uncertainty in formation hydraulic parameter estimates is not quantifiable unless actual test-specific C_{tz} data are used.

At completion of the PI tests, the pulse piston was retracted to initiate a brief PW. This allowed verification that the same magnitude pulse was created by piston retraction as was created by piston extension at the start of the test. This confirmed that C_{tz} was constant over the test duration.

3.7 Test Termination

After a test was terminated, the DHSIV was opened, the packers were deflated, data acquisition terminated, and the raw test data file was produced. The file (CSV format) contained date/time stamps and pressure responses for all real-time transducers. The file was imported into nSIGHTS to produce a set of reference plots to be included with the DQC workbook.

3.8 Real-Time Analysis

The nSIGHTS well-test-analysis software (Section 4) was used to provide preliminary estimates of formation properties as testing progressed. Test-zone pressure histories were constructed for each testing sequence using the relevant data starting from drilling intercept to the start of the current sequence and were included in the analyses.

The measured test response for the equilibration/stabilization period during a testing sequence formed an additional pre-test history sequence. As a test progressed, measured TZ pressures were used to update the test sequence and the analysis continued. A final optimization with all the test data was performed immediately following test termination. These preliminary test analyses were recorded in the DQCW describing test results. All real-time analysis results are superseded by analyses presented in this report.

4 ANALYSIS APPROACH

A discussion of the conceptual flow models, descriptions of the types of hydraulic tests performed, definitions of the various fitting parameters, a discussion on borehole pressure history, and an overview of the analysis process, including the uncertainty calculations, are given below.

4.1 Conceptual Model

The term *conceptual model* in this report refers to the mathematical description of the hydrogeologic system. Selecting a conceptual model is the first step in the overall analysis process. The choice of conceptual model, along with the type of hydraulic test(s) performed, determines which parameters will be estimated, i.e., which parameters will be fitting parameters in the analysis process.

In a near horizontally layered sedimentary sequence, like that tested in borehole SB_BH02, where the borehole is drilled approximately perpendicular to the layers, the simplest conceptual model that is generally invoked in well-test analysis is described as an infinite-acting, radial-flow system with wellbore storage and skin. *Infinite-acting* means that the hydraulic parameters controlling the test response, such as transmissivity (T) and storativity (S), are constant within the region affected by the test and the test is not affected by external boundary conditions. The term radial indicates horizontal convergent flow toward and/or away from the test zone (depending on the gradient induced during a test). Note that all flow is assumed to be horizontal within the tested layer, i.e., flow with no vertical component. A further assumption made in the conceptual model is that the hydraulic properties of the tested interval do not vary vertically. This assumption may not hold true when multiple formations are included in the test interval.

Wellbore storage is that property of the testing system whereby some portion of the fluid injected/withdrawn during a hydraulic test is taken up by / derived from the test zone (shut-in valve is closed) or the tubing (shut-in valve is open) rather than the formation. During the wellbore-storage dominated period of a test, the formation properties of interest have little effect on the observed pressure response, meaning the formation properties are masked to some extent. The wellbore-storage dominated period of a test is that period in a test where the total system compressibility acts to mask the formation pressure response by absorbing/producing fluid unrelated to fluid movement in/out of the formation. Ideally, a test will proceed long enough such that the formation-flow component dominates the wellbore-storage component and the formation properties can be reliably estimated. The adequacy of the SB_BH02 test durations was determined by real-time analysis.

An area of altered hydraulic conductivity surrounding the wellbore that results from drilling activities (e.g., mud infiltration, stress relief, etc.) is termed a skin. A positive skin is a zone in which K has been decreased relative to the unaltered formation K. A negative skin is a zone in which K near the wellbore has been enhanced. Skin was included in all SB_BH02 simulations and was implemented using nSIGHTS' radially varying hydraulic conductivity functionality in which hydraulic conductivity changes logarithmically as a function of distance. A fixed radius point was placed at the wellbore with hydraulic conductivity optimized to represent initial skin conductivity. An adjustable radius point was placed to define the skin thickness and the optimized formation hydraulic conductivity. Formation hydraulic conductivity was constant beyond this adjustable radius point.

4.2 Parameters

Hydraulic conductivity (K) [L/T] is a constant of proportionality that was empirically derived by Darcy (1856) expressing the ratio of fluid flux to gradient within a porous medium. Darcy's empirical relationship is generally referred to as Darcy's Law, and can be written as follows:

$$Q = -K \frac{dh}{dl} A \quad \text{Equation 4-1}$$

where:

$$\begin{aligned} Q &= \text{flow rate} & [L^3/T] \\ dh/dl &= \text{hydraulic gradient} & [] \\ A &= \text{flow area} & [L^2] \end{aligned}$$

The specific storage (S_s) [1/L] of a saturated geologic unit describes the amount of fluid released as a function of both the rock and fluid compressibility per unit decline in hydraulic head per unit volume of rock, and is given as:

$$S_s = \rho g (\alpha + n\beta) \quad \text{Equation 4-2}$$

where:

$$\begin{aligned} \rho &= \text{fluid density} & [M/L^3] \\ g &= \text{gravity} & [L/T^2] \\ \alpha &= \text{rock compressibility} & [LT^2/M] \\ n &= \text{porosity} & [] \\ \beta &= \text{fluid compressibility} & [LT^2/M] \end{aligned}$$

Well-test analysis does not provide estimates of K and S_s, but of their products when multiplied by the test-interval length, transmissivity (T) [L²/T] and storativity (S) [-]. For the analyses presented in this report, K and S_s were calculated by assuming that all test intervals were vertically homogeneous and simply dividing the inferred values of T and S by the test-interval length. The validity of this assumption undoubtedly varies from test interval to test interval; when a test interval is wholly contained within a single formation, vertical homogeneity may be a reasonable assumption. But when a test interval spans portions of several formations, the assumption is less defensible. In such a case, other information must be used to try to infer what portion of the total T (or S) is contributed by the K (or S_s) and thickness of each formation in the test interval.

Static formation pressure (P_f) [M/LT²] is the undisturbed fluid pressure within a formation prior to drilling and testing. "Raw", or uncorrected, formation pressures are those measured by the transducer, which is located some distance above the centre of the test zone. These "raw" numbers are used in the individual test analyses presented below. The raw values are subsequently corrected to represent the pressure in the centre of the test interval. Borehole fluid density estimates and measured transducer locations are used in calculating corrections. The corrected values are presented in the test summary tables and the borehole summary tables (Section 7).

The observed pressure change ($\Delta Pressure$) in the isolated test zone for a given amount of fluid ($\Delta Volume$) that enters/leaves the test zone is controlled by the test-zone compressibility (C_{tz}), defined as follows:

$$C_{tz} = \frac{1}{TotalVolume} \frac{\Delta Volume}{\Delta Pressure} \quad \text{Equation 4-3}$$

where: $Total Volume$ = total volume of fluid within the isolated test zone

The skin factor (s) [] is a dimensionless parameter that indicates the relative degree to which skin hydraulic conductivity (K_s) near the borehole differs from the undisturbed formation hydraulic conductivity (K_f) at some distance away from the borehole. The skin factor is defined by Hawkins (1956) as:

$$s = \left(\frac{K_f}{K_s} - 1 \right) \times \ln \left(\frac{(r_w + t_s)}{r_w} \right) \quad \text{Equation 4-4}$$

where:

r_w = nominal well radius [L]
 t_s = skin thickness [L]

In the case where the value of K_s is changing logarithmically with distance from the borehole wall to the value of K_f , the value of K_s used in Equation 4-4 is the log average of K_s at the borehole wall (which is the value fitted by nSIGHTS) and K_f .

4.3 Tests

A pulse injection (PI) or pulse withdrawal (PW) test is an instantaneous (within the limitations of the equipment) pressure increase or decrease induced in the test zone that is subsequently allowed to dissipate back toward static pressure conditions. The rate of pressure decay is used to infer the hydraulic properties of the tested geologic unit. During a pulse test, the test zone is shut-in, i.e., it is isolated from the fluid column in the tubing by closing the shut-in valve. Pulse tests are most suitable for testing formations with hydraulic conductivities less than 1E-10 m/s, and were performed in the majority of the test intervals.

Compressibility of the SB_BH02 test zones was calculated for each pulse test. All SB_BH02 pulse tests were initiated by rapidly extending the downhole pulse piston of known volume. The C_{tz} was then calculated from Equation 4-3 by measuring the initial pressure change, given that the test-zone fluid volume was known. (Note that the test-zone fluid volume comprises the fluid in the borehole between the two packers as well as all fluid contained within the test tool below the shut-in valve.) Note that hydraulic parameters such as K cannot be estimated accurately from pulse responses without knowing C_{tz} . All pulse tests performed in SB_BH02 used an initial PI, followed by a PW at the end of the test to confirm C_{tz} .

Slug withdrawal (SW) tests are similar to pulse tests, but the shut-in valve remains open during a slug test and fluid flowing out of the formation results in changing water levels within the tubing. Slug tests were initiated by removing water from the tubing to a desired level while the shut-in valve was closed, and then rapidly opening the shut-in valve. Analogous to C_{tz} in a pulse test, the tubing radius and fluid

density controlled the observed pressure change for a given amount of fluid that entered/left the tested formation. The tubing string radius must be known to estimate K from a slug-test response.

4.4 Formation Specific Storage - Skin Conductivity - Skin Thickness

Simultaneously estimating S_s , skin K (K_s), and skin thickness (t_s) values from analysis of single-well data (i.e., no cross-hole response) is complicated by the high degree of correlation among these fitting parameters in the regression process. Figure 4.1 shows 1345 estimates of these three parameters obtained from perturbation analysis (Section 4.6) of an example pulse test conducted in a low-permeability sedimentary formation. Note that each of the 1345 solution sets produced effectively equivalent matches (small change in the fit value) to the measured response. The values of K_s and t_s can be simultaneously increased/decreased over a range that results in approximately the same skin factor, s (Equation 4-4).

Figure 4.1 An X-Y-Z scatter plot showing the correlation among skin thickness, skin hydraulic conductivity, and specific storage that can occur in a single-well test.

In addition, S_s and s affect the match to a single-well pressure response in much the same way, so they can be simultaneously changed to produce a series of equivalent matches. Figure 4.2 shows simulated pulse-test responses assuming equilibrium initial conditions plotted on a log-log scale as a normalized pressure response and its derivative; a standard well-test diagnostic plot known as a Ramey B plot

(Ramey et al., 1975). Various parameter possibilities are simulated to illustrate the difficulty in distinguishing among variations in S_s and s .

Figure 4.2 Ramey B diagnostic plots showing various combinations of skin factors and formation specific storage.

The baseline example shown in red in Figure 4.2 shows simulated responses when the hydraulic properties around the wellbore have not been altered – a condition known as a “zero” skin. Note that S_s for the baseline case is $1E-7 \text{ m}^{-1}$ and the formation K (K_f) for all examples is constant. When the drilling process results in increased K_s over some distance t_s near the wellbore relative to the unaltered formation K_f , the condition is known as a “negative” skin, plotted as a blue line in Figure 4.2. Notice that the negative skin produces a distinctive downward inflection in that part of the Ramey B derivative that appears as an upward-sloping straight line when no skin is present (timing and magnitude of this inflection depend on the contrast between skin and formation properties). This inflection is observed in most of the DGR pulse responses. A decrease in K_s over some distance t_s around the wellbore is known as a “positive” skin, plotted in green in Figure 4.2. Unlike the negative skin, a positive skin causes no distinct inflection in the Ramey B derivative; it simply changes the slope of the derivative (the pulse recovery is slowed), effectively translating it to the right on the graph relative to the zero-skin case. Shown in magenta and gold are two zero-skin examples where S_s has been increased to $1E-6 \text{ m}^{-1}$ and decreased to $1E-8 \text{ m}^{-1}$, respectively. As with the positive-skin case, simply changing the value of S_s does not result in a notable inflection in the derivative, it primarily changes the position of the derivative with respect to the baseline case. Figure 4.1 shows that changing K_s or S_s can result in similar responses, and consequently, estimates for each of these parameters can be paired in non-unique combinations to achieve similar matches to field data. In the case where the initial conditions at the start of a pulse are transient rather than in equilibrium (i.e., pressure is still responding to borehole history), the early-time derivative response may be altered from what is shown in Figure 4.2. Under these conditions, an inflection in the early-time derivative reflects the presence of a skin, but not whether it is positive or negative. Also note that any small transient changes in test-tool position or packer shape at the start of a pulse or slug test can affect the pressure response in such a way that these non-

formation responses resemble a skin effect. The approach used in these analyses for estimating Ss is discussed below in Section 4.7.

4.5 Pre-Test Borehole History

Each nSIGHTS simulation description includes a detailed specification of the sequence of borehole boundary conditions from the point at which the borehole perturbs the in situ, or formation, pressure. The sequence of pressures experienced by a test interval during the period between interception of the interval by drilling and the start of testing is denoted the "pressure history".

Pressure histories were included in the analyses performed for each test interval as specified-pressure boundary conditions in the test zone. Part of the pressure history consisted of the calculated pressure (not measured by transducer) at the centre of each test interval from the approximate time of drilling intercept to the time that the pressure at that interval was measured by a pressure transducer.

Fluid densities recorded during drilling and logging were nominally 1100 g/L with some measurements as low as 1046 g/L. There were drilling fluid losses after drilling through and below permeable Silurian formations, primarily the Guelph. After completion of drilling, borehole fluid equilibration occurred as native formation fluids from permeable intervals mixed with higher density drilling fluids that had migrated into these formations during drilling. It is assumed that borehole pressures would remain relatively constant as Guelph formation pressures dictated overall borehole response. Accordingly, the borehole pressure history prior to testing was fixed at the first measured pressure at the start of the first test (HT01_05).

After the start of straddle-packer testing in a given interval, pressure histories are extracted from measured pressures in the annulus and bottom zones of previous tests. As an illustrative example, the borehole history for the 29.96-m test conducted in the Collingwood/Upper Cobourg (HT10_30) is shown in Figure 4.3. The constant pressure from drilling intercept until start of HT testing reflects the TZ pressure measured at the beginning of HT01_05. Tests conducted above the permeable Guelph Formation did not result in significant BZ pressure changes. However, subsequent tests on lower intervals all showed an under-pressured response in the BZ which is included in the borehole history. Measured BZ pressures were adjusted to the center of the test interval using the average borehole fluid density.

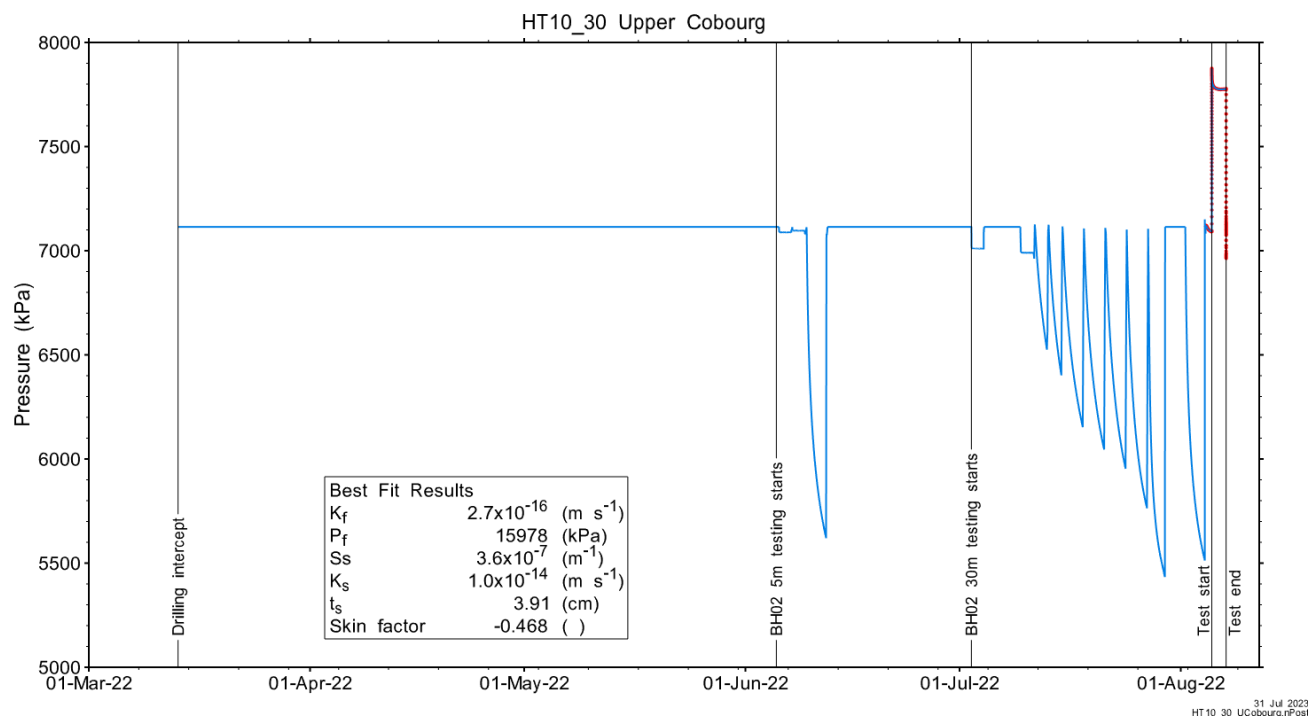

Figure 4.3 Pre-test borehole history for test HT10_30.

4.6 Test Zone Thermal Effects

Temperature changes in the shut-in test zone during pulse tests will cause thermal expansion or contraction of the borehole fluid, leading to pressure changes which complicate the analyses. Although nSIGHTS has the capability of including thermal effects in analyses, this leads to additional uncertainties in analysis results. Test zone temperatures for the three 5 m pulse tests in SB_BH02 (Figure 4.4) showed no evidence of thermal effects. All analyses were conducted as isothermal.

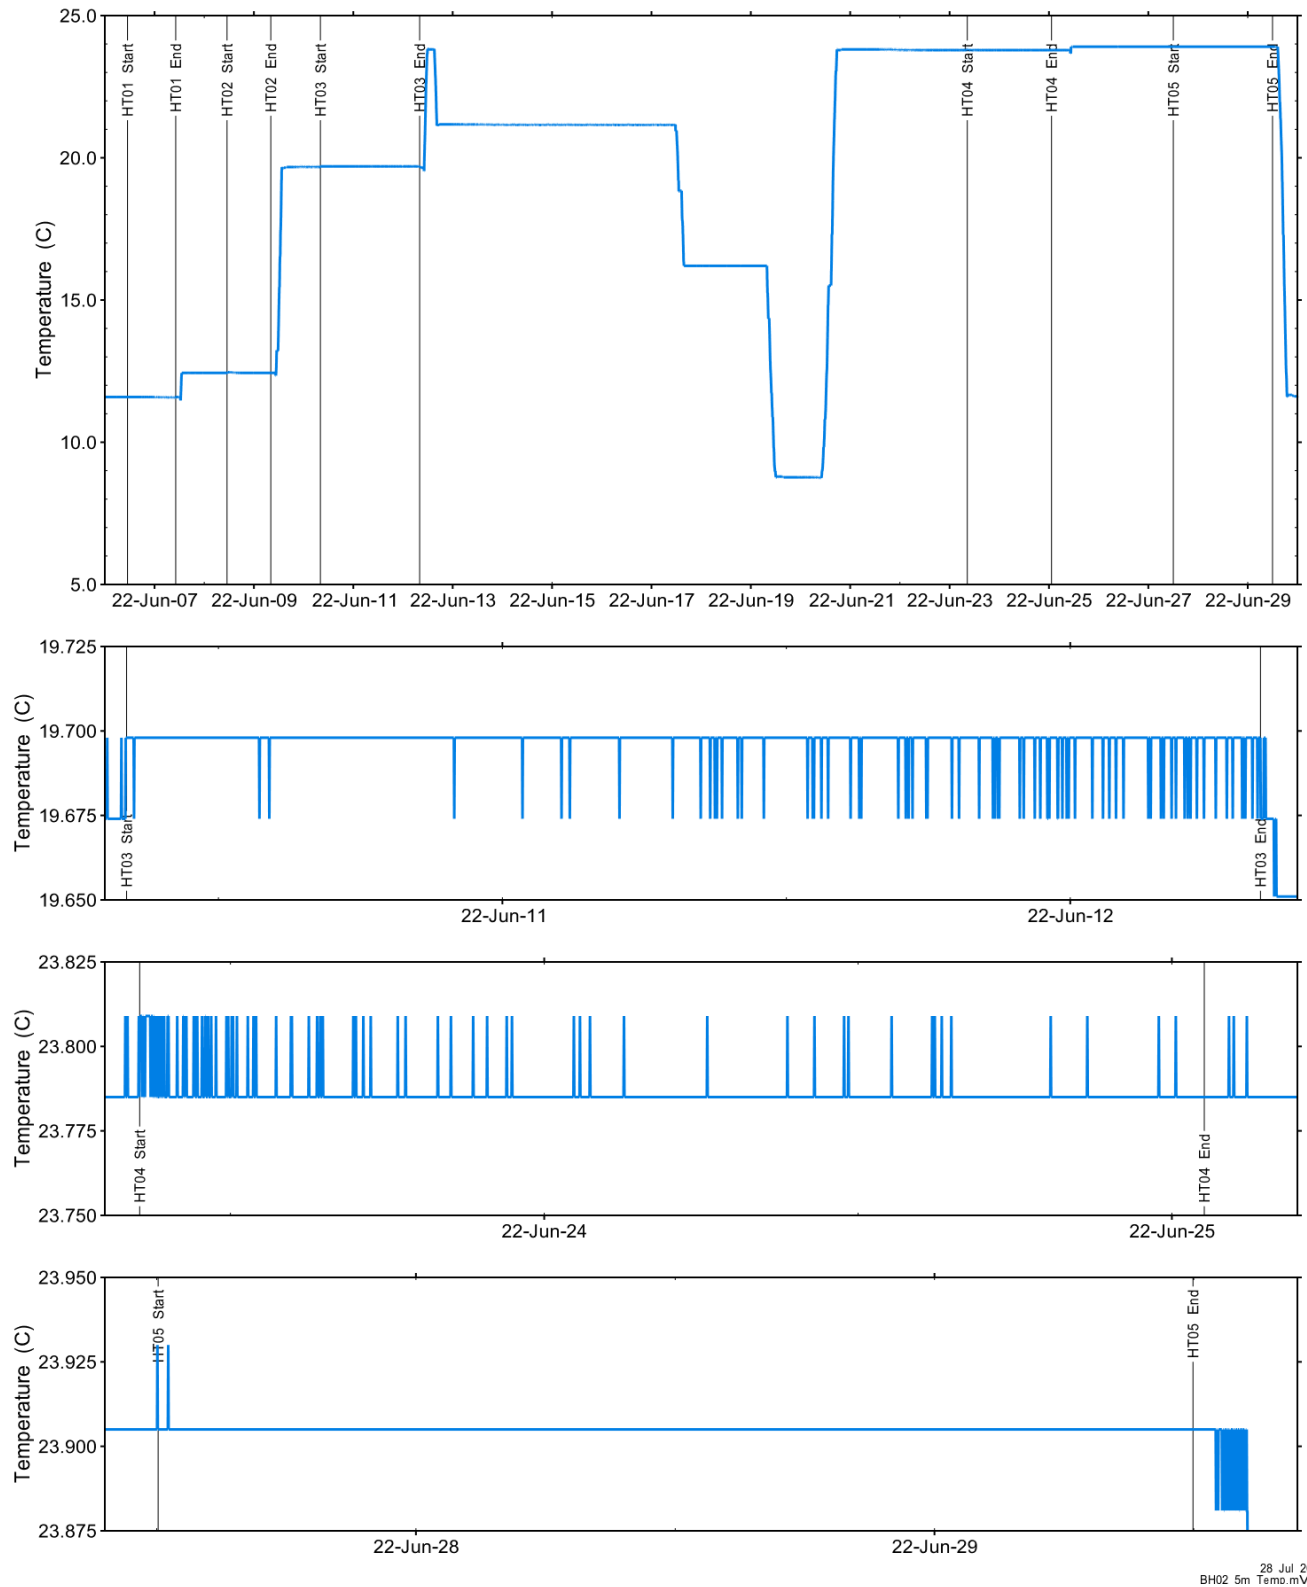

Figure 4.4 Test zone temperature during 5 m pulse tests in SB_BH02.

4.7 Uncertainty Analysis

All tests analyzed in this report assumed the skin conceptual model described in Section 4.1, which requires five fitting parameters: K_f , P_f , K_s , t_s , and S_s . Preliminary analyses obtained a single set of optimized baseline fitting-parameter values. These were used to determine limiting ranges, or domains, for each optimized parameter. Perturbation analyses were then performed to obtain the final best-fit parameter values and the corresponding uncertainty ranges.

For these analyses, 10,000 simulations were performed using randomized starting parameter estimates uniformly distributed over the potential parameter domain. Simulations which converged on an optimized solution (typically the vast majority of the 10,000 perturbations) were retained for further analyses. Initial and converged parameter estimates for selected parameters in the HT13_30 test analyses are shown in Figure 4.5 through Figure 4.8. Each figure shows data for three parameter domains – K_f is shown on all figures.

Figure 4.8 Converged parameter estimates for K_f , S_s , and t_s (HT13_30).

Goodness-of-fit is determined by the fit value, which is the sum-of-squared errors (SSE) between the simulated response and the TZ pressure data. Fit-values were normalized to the minimum (or best fit) value and the cumulative distribution function (CDF) calculated. The structure of the CDF was then examined and a “fit-discriminant” value determined. Generally, the fit discriminant was set at the first value where the CDF shape changes or inflects. A secondary criterion was to ensure that all selected fits closely matched the TZ field data. All fits with fit-values less than the discriminant were accepted as being representative of the formation response. This approach limits the fits to those within the apparent global minimum of the five-dimensional parameter space. Typically, at least several hundred perturbations were accepted for each test. Figure 4.9 shows the normalized fit CDF and the fit discriminant for the HT13_30 test.

Figure 4.9 Normalized fit CDF (HT13_30).

Examination of individual fit distributions (Figure 4.10) provides confirmation that local minima are not included.

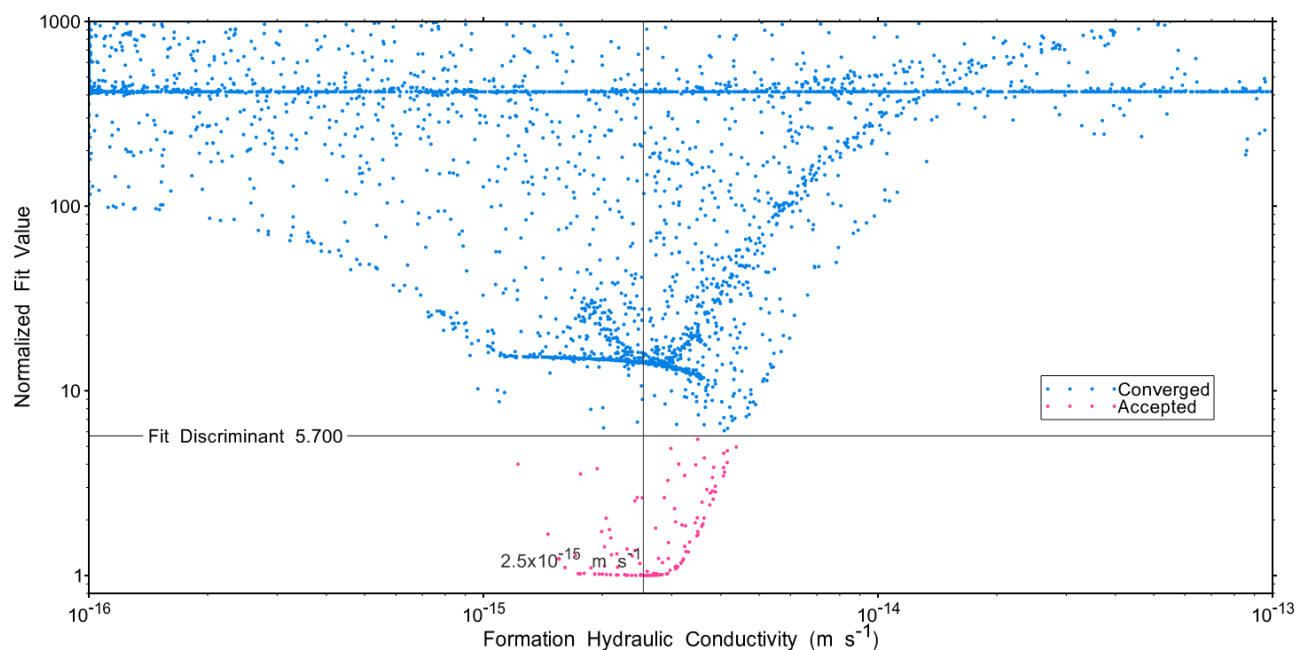

Figure 4.10 Fit distribution for K_f (HT13_30).

The parameter estimates and fit values for the 661 perturbations that met the fit-discriminant value are shown in Figure 4.11 and Figure 4.12.

Figure 4.11 Accepted estimates for K_f , K_s , and P_f with fit values and best-fit (HT13_30).

Figure 4.12 Accepted estimates for K_f , S_s , and t_s with fit values and best-fit (HT13_30).

CDFs were constructed for each of the estimated parameters from the accepted perturbations to determine parameter uncertainty. The parameter CDF for K_f is constructed for all accepted values below the fit-discriminant line in Figure 4.10, and is shown in Figure 4.13.

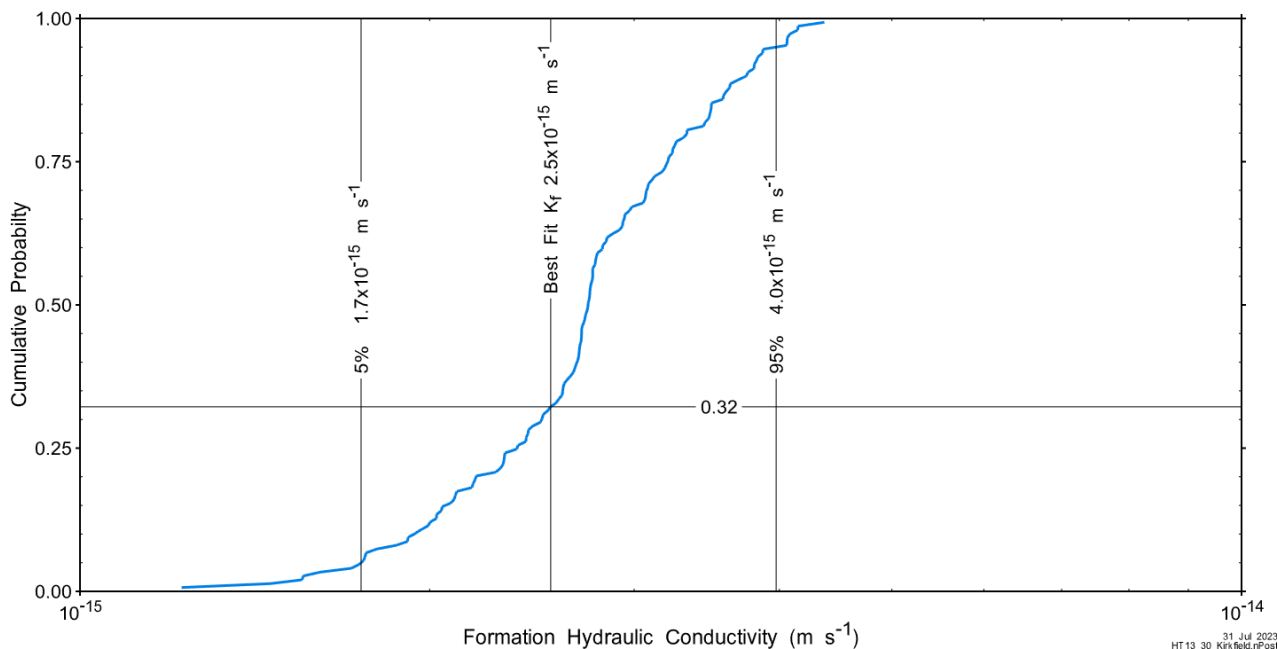

Figure 4.13 Cumulative distribution of accepted formation hydraulic conductivity (HT13_30). Simulated results for all perturbations where all accepted parameter values were within the 5% to 95% range are shown in Figure 4.14. Note that the blue line shows results for all 123 perturbations with all parameters in the 5% to 95% range.

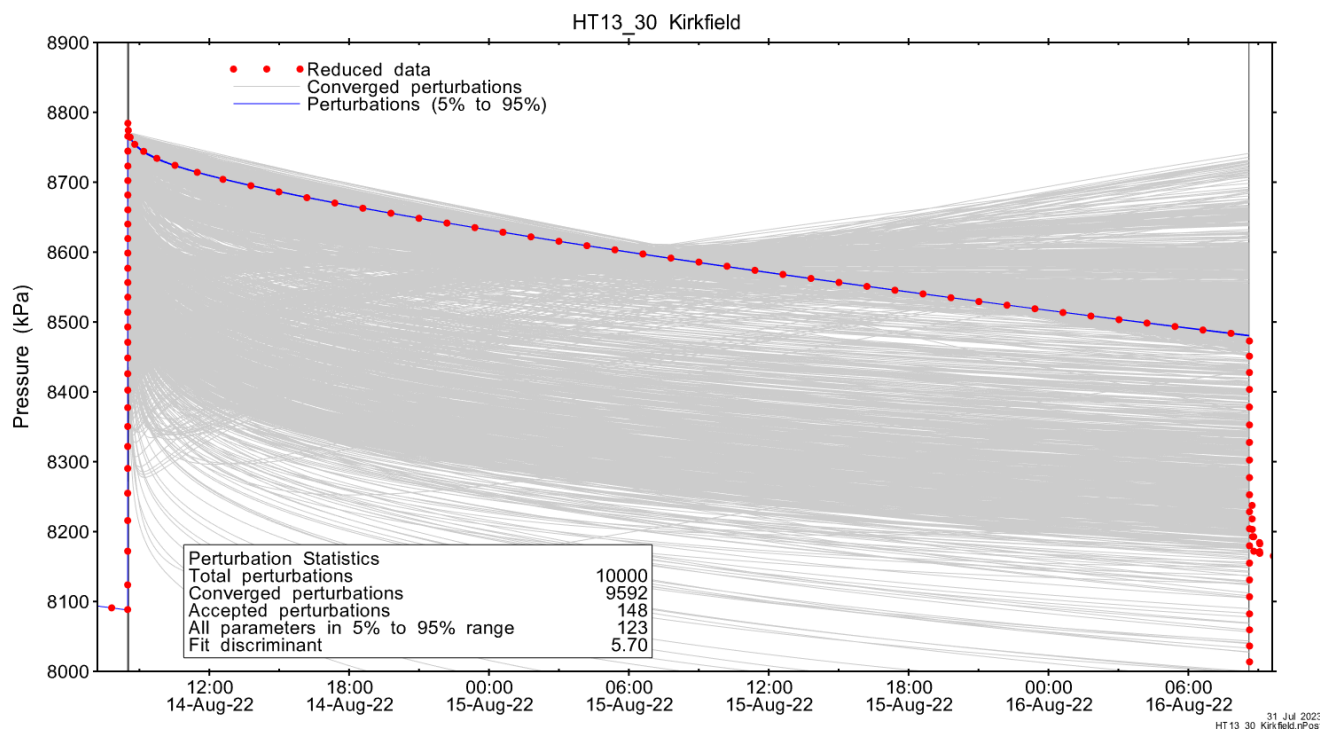

Figure 4.14 Horsetail plot showing perturbation results.

Ramey B processed results (Figure 4.15) illustrate the uncertainty range in processed derivatives.

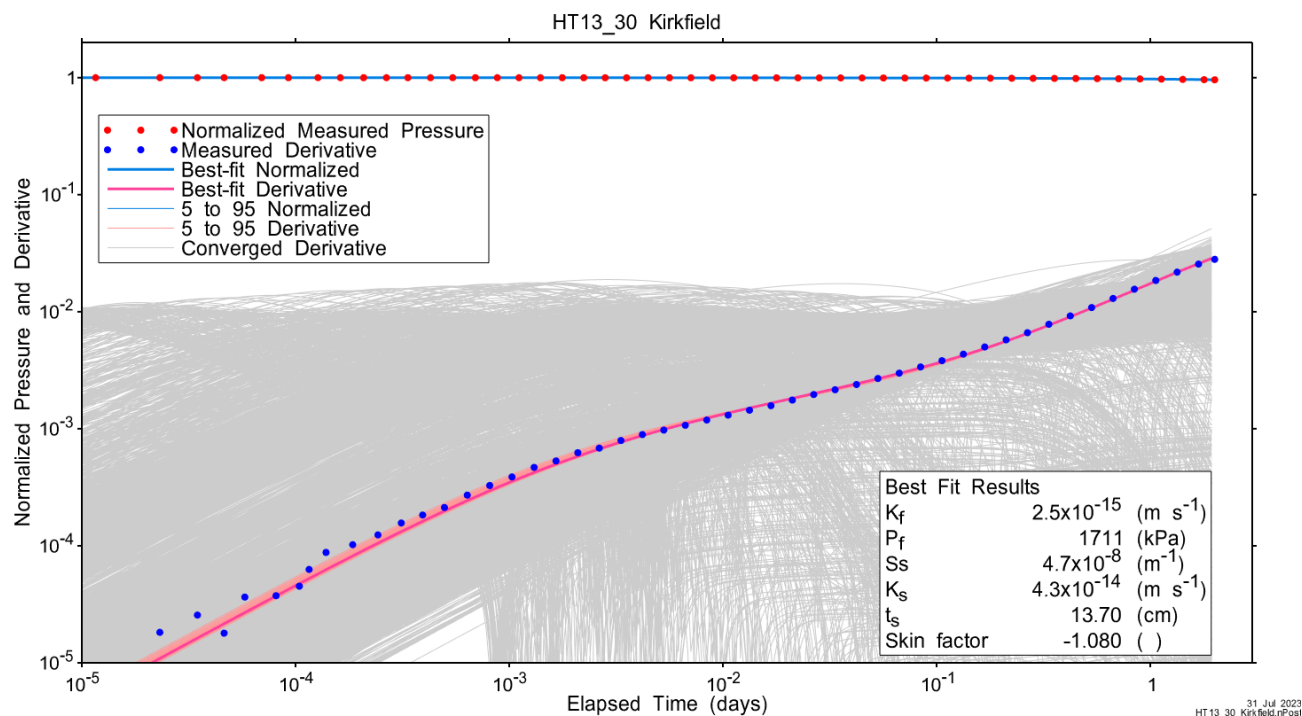

Figure 4.15 Ramey B processed horsetail plot showing perturbation results (HT13_30).

As a final analysis, fitted parameter correlations are calculated for all accepted optimizations (Table 4.1).

Table 4.1 Pearson cross-correlations of 5% to 95% parameters (HT13_30).

	Log(K_f)	P_f	Log(S_s)	Log(K_s)	t_s	s
Log(K_f)	1.000	0.965	-0.686	0.859	0.617	-0.647
P_f	0.965	1.000	-0.493	0.708	0.439	-0.452
Log(S_s)	-0.686	-0.493	1.000	-0.954	-0.976	0.998
Log(K_s)	0.859	0.708	-0.954	1.000	0.897	-0.936

s	-0.647	-0.452	0.998	-0.936	-0.984	1.000

5 TEST INTERVALS

Test intervals were selected by Geofirma in consultation with NWMO staff. In general, individual formations were targeted, with most testing focussed on the Ordovician-age formations. The shorter 5-m tests were assigned to relatively thin formations. Within individual formations, test intervals were adjusted vertically to ensure packer seats were located in zones with minimal borehole diameter changes as indicated by caliper logs. Borehole geophysical logs, core photos and core logging data were also reviewed during the interval selection process. Intervals were selected based on nominal 30-m and 5-m interval lengths. These have been corrected to the actual 29.96-m and 5.03-m test interval lengths resulting from selection of available tubing and pup joints during testing. Test durations were specified as 2 days for all tests above the Queenston Formation shale, and 3 days for Queenston Formation shale and deeper tests. This provided longer test response times for the lower permeability Ordovician formations.

The Cobourg Formation and Collingwood Member were targeted with three tests: two 30-m intervals which overlapped to give complete coverage of the Cobourg (HT10_30 and HT11_30), and a single 5-m test for the Collingwood Member (HT03_05). However, formation tops were subsequently revised and the Collingwood Member top adjusted downward by approximately 8 m, resulting in the 5-m “Collingwood” test interval being totally encompassed in the lower Blue Mountain Formation. Similarly, the 30-m test designed to cover the top 30 m of the Cobourg Formation (HT10_30) ended up consisting of 6.47 m of the Collingwood and the upper 23.53 m of the Cobourg. These tests have been renamed appropriately.

Table 5.1 and Figure 5.1 summarize the selected test intervals. The third panel of the figure presents caliper data and the mean caliper values for each test interval. Mean caliper values were used as the well radius in nSIGHTS analyses. Logged core features are presented in the fourth panel of the figure.

Table 5.1 SB_BH02 hydraulic testing intervals.

Test ID	Top (mBGS)	Bottom (mBGS)	Formation	Caliper Mean Diameter (cm)	Specified Packer Pressure (psi)
5-m Tests					
HT01_05	332.50	337.53	Salina A2 Evaporite	13.49	1150
HT02_05	386.80	391.83	Guelph	13.09	1700
HT03_05	663.50	668.53	Blue Mountain - Lower	12.77	1700
HT04_05	880.50	885.03	Shadow Lake	12.50	1700
HT05_05	887.00	892.03	Precambrian	12.24	1700
30-m Tests					
HT01_30	200.00	229.96	Salina F	13.26	1200
HT02_30	340.00	369.96	Salina A1 Carbonate	13.45	1250
HT03_30	393.00	422.96	Goat Island	13.42	1600
HT04_30	420.00	449.96	Cabot Head	13.34	1700
HT05_30	450.00	479.96	Queenston – Upper	14.90	1700

HT15_30	840.00	869.96	Gull River	12.49	1700

6 INDIVIDUAL TEST ANALYSES

All analyses follow a common structure:

1. Test Data Summary – a table describing timing and duration of test events and a figure displaying pressures for all downhole pressure transducers over the period of active testing.
2. Test Analyses – tables showing test-specific nSIGHTS input parameters and ranges for optimized fitting parameters. Figures are presented showing: a) the single-best fit result, b) the borehole history, c) the Ramey B plot for the best fit, and d) the normalized Jacobian parameter sensitivity plot.
3. Uncertainty Analyses – figures include: a) the CDF of normalized fit values annotated with the selected fit discriminant, b) cross plots (K_f vs P_f , K_f vs S_s , P_f vs S_s , and K_s vs t_s) showing initial parameter estimates, converged simulations and simulations meeting fit-discriminant criteria, c) parameter CDFs for all simulations meeting fit-discriminant criteria, d) horsetail Cartesian and Ramey B plots showing converged and accepted simulations, e) tables summarizing parameter ranges (best fit, 5%, median, and 95%) and fitted parameter correlations.
4. Additional Figures – includes: a) hydraulic system pressures and weather data (barometric pressure, surface temperature), and b) structure of normalized fit values for each fitted parameter.

Individual test analyses are presented in Appendix A.1 through A.20.

7 ANALYSES SUMMARY

Results from analyses documented in Appendix A are presented in summary form by test interval.

7.1 Summary Tables

CDFs of all accepted perturbations for each parameter represent the range of values for which analyses are visually indistinguishable on a Cartesian plot. The “Best Fit”, 5%, Median (50%), and 95% CDF values are extracted for each parameter to indicate the possible range of parameter values. The “Best Fit” value represents the minimum SSE for all accepted perturbations but should not be considered as the most representative value, as occasionally the Best Fit falls outside the 5% and 95% confidence interval range. The Median value should be used as the representative single value for each parameter.

Table 7.1 through Table 7.6 provide the Best Fit, 5%, Median (50%), and 95% CDF values for each fitting parameter and for the calculated skin factor. Formation pressures (Table 7.2) are adjusted to the interval midpoint. A final table shows simulation input parameters (Table 7.7).

As described in Appendix A.15, the analyses of the HT10_30 test of the Collingwood and Upper Cobourg yielded anomalous formation pressure estimates and very low hydraulic conductivity estimates. We believe these results are due to the extremely low hydraulic conductivity which is below the lower limit of tool capability with the amount of time available for testing. Accordingly, the formation hydraulic conductivity estimate for this interval is reported as less than 10^{-15} m/s; other parameters for this interval are not reported.

Table 7.1 SB_BH02 Summary of Formation Hydraulic Conductivity Estimates.

Formation Hydraulic Conductivity (m/s)					
Test ID	Formation	Best Fit	5%	Median	95%
HT01_30	Salina F	1.8E-14	1.0E-14	5.7E-14	8.7E-14
HT02_30	Salina A1 Carbonate	7.8E-12	7.0E-12	1.1E-11	1.7E-11
HT03_30	Goat Island	1.4E-07	1.0E-07	1.5E-07	2.1E-07
HT04_30	Cabot Head	4.7E-14	3.5E-14	5.2E-14	9.9E-14
HT05_30	Queenston – Upper	3.0E-13	2.4E-13	1.1E-12	3.4E-12
HT06_30	Queenston – Lower	5.3E-12	5.1E-12	3.9E-10	8.6E-09
HT07_30	Georgian Bay – Upper	4.2E-14	1.3E-14	4.1E-14	4.2E-14
HT08_30	Georgian Bay – Lower	2.6E-09	3.3E-11	4.2E-09	8.1E-08
HT09_30	Blue Mountain	2.1E-15	3.9E-15	1.1E-13	1.6E-13
HT10_30	Collingwood/Cobourg	<1E-15			
HT11_30	Cobourg	1.6E-15	1.0E-15	1.7E-15	3.1E-15

7.2 Summary Figures

Figure 7.1 and Figure 7.2 show the Best Fit, 5%, Median, and 95% CDF values for each fitting parameter and for the calculated skin factor plotted against the stratigraphy. Formation pressures (Figure 7.1) are adjusted to the interval midpoint. The Silurian strata are generally normally pressured, whereas the majority of the lower Ordovician strata show significant under-pressures. Test-specific simulation input parameters are presented in Figure 7.3.

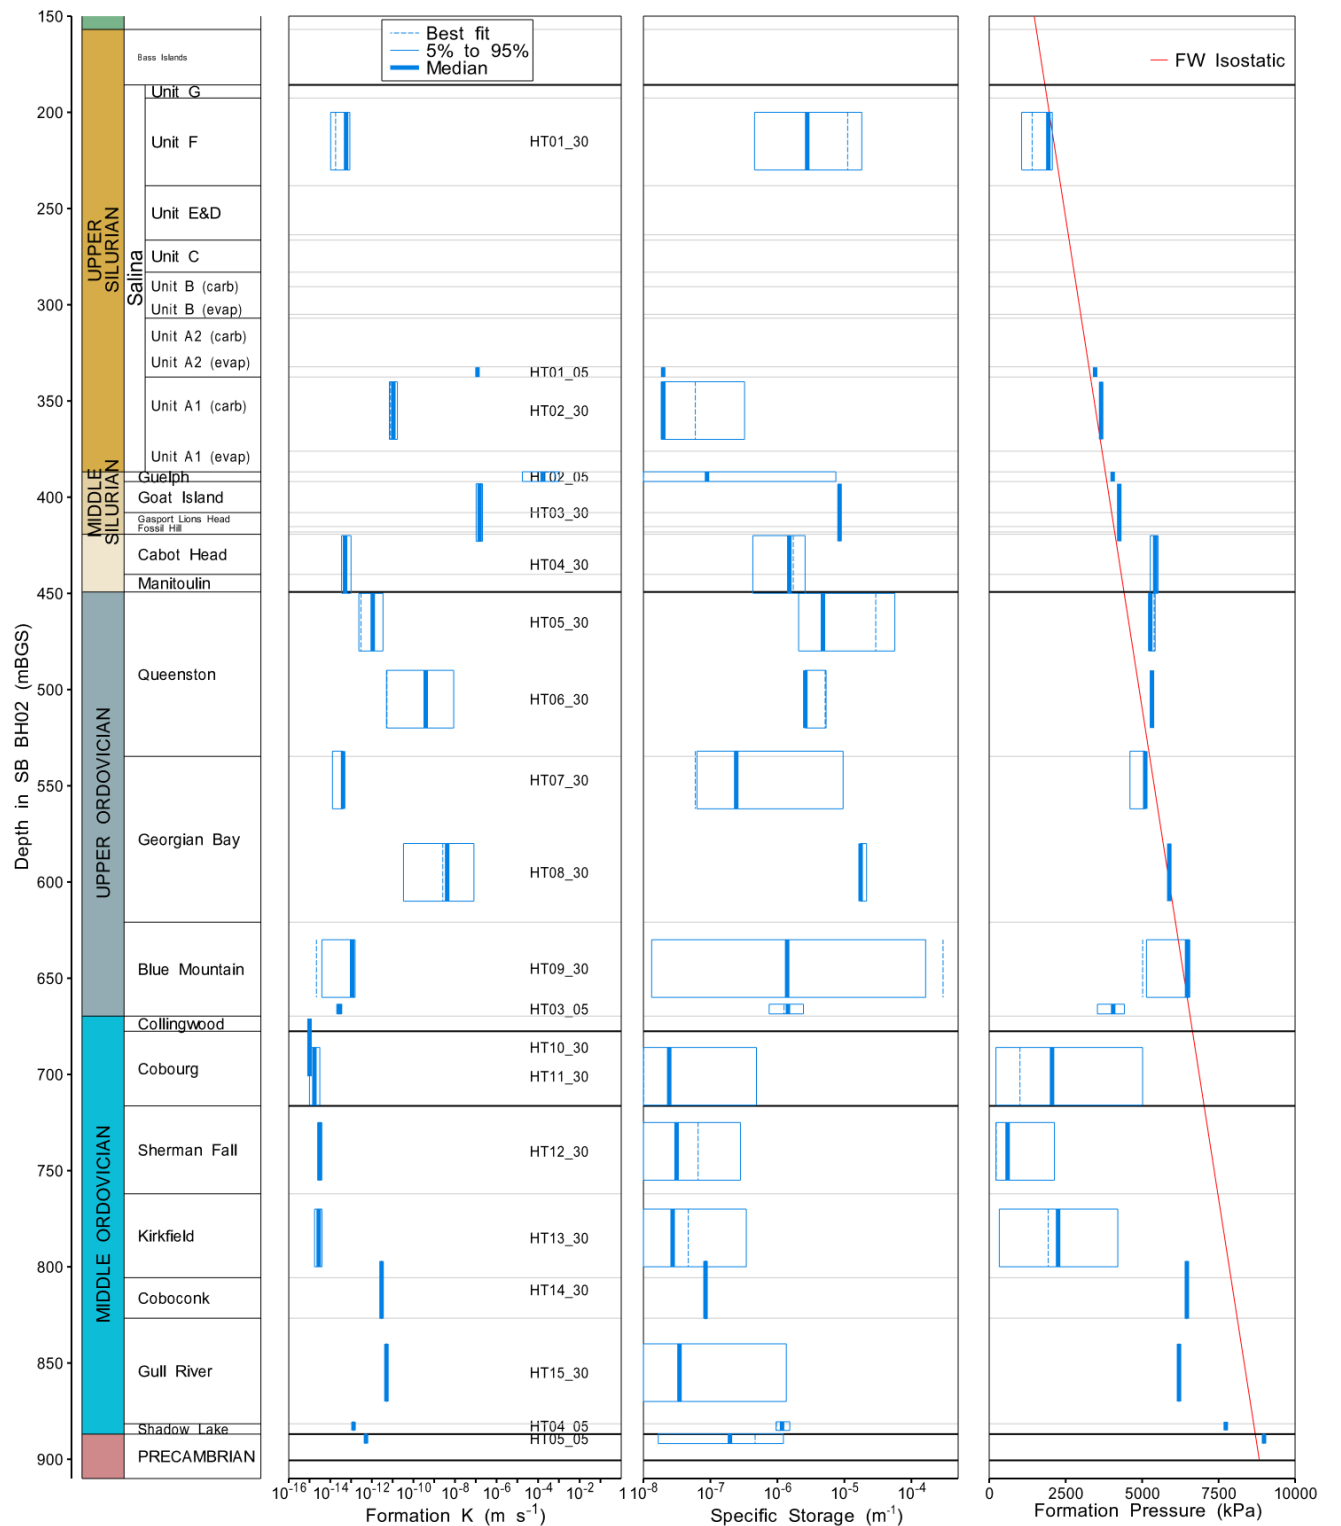

Figure 7.1 Formation Hydraulic Conductivity, Specific Storage and Adjusted Formation Pressure.

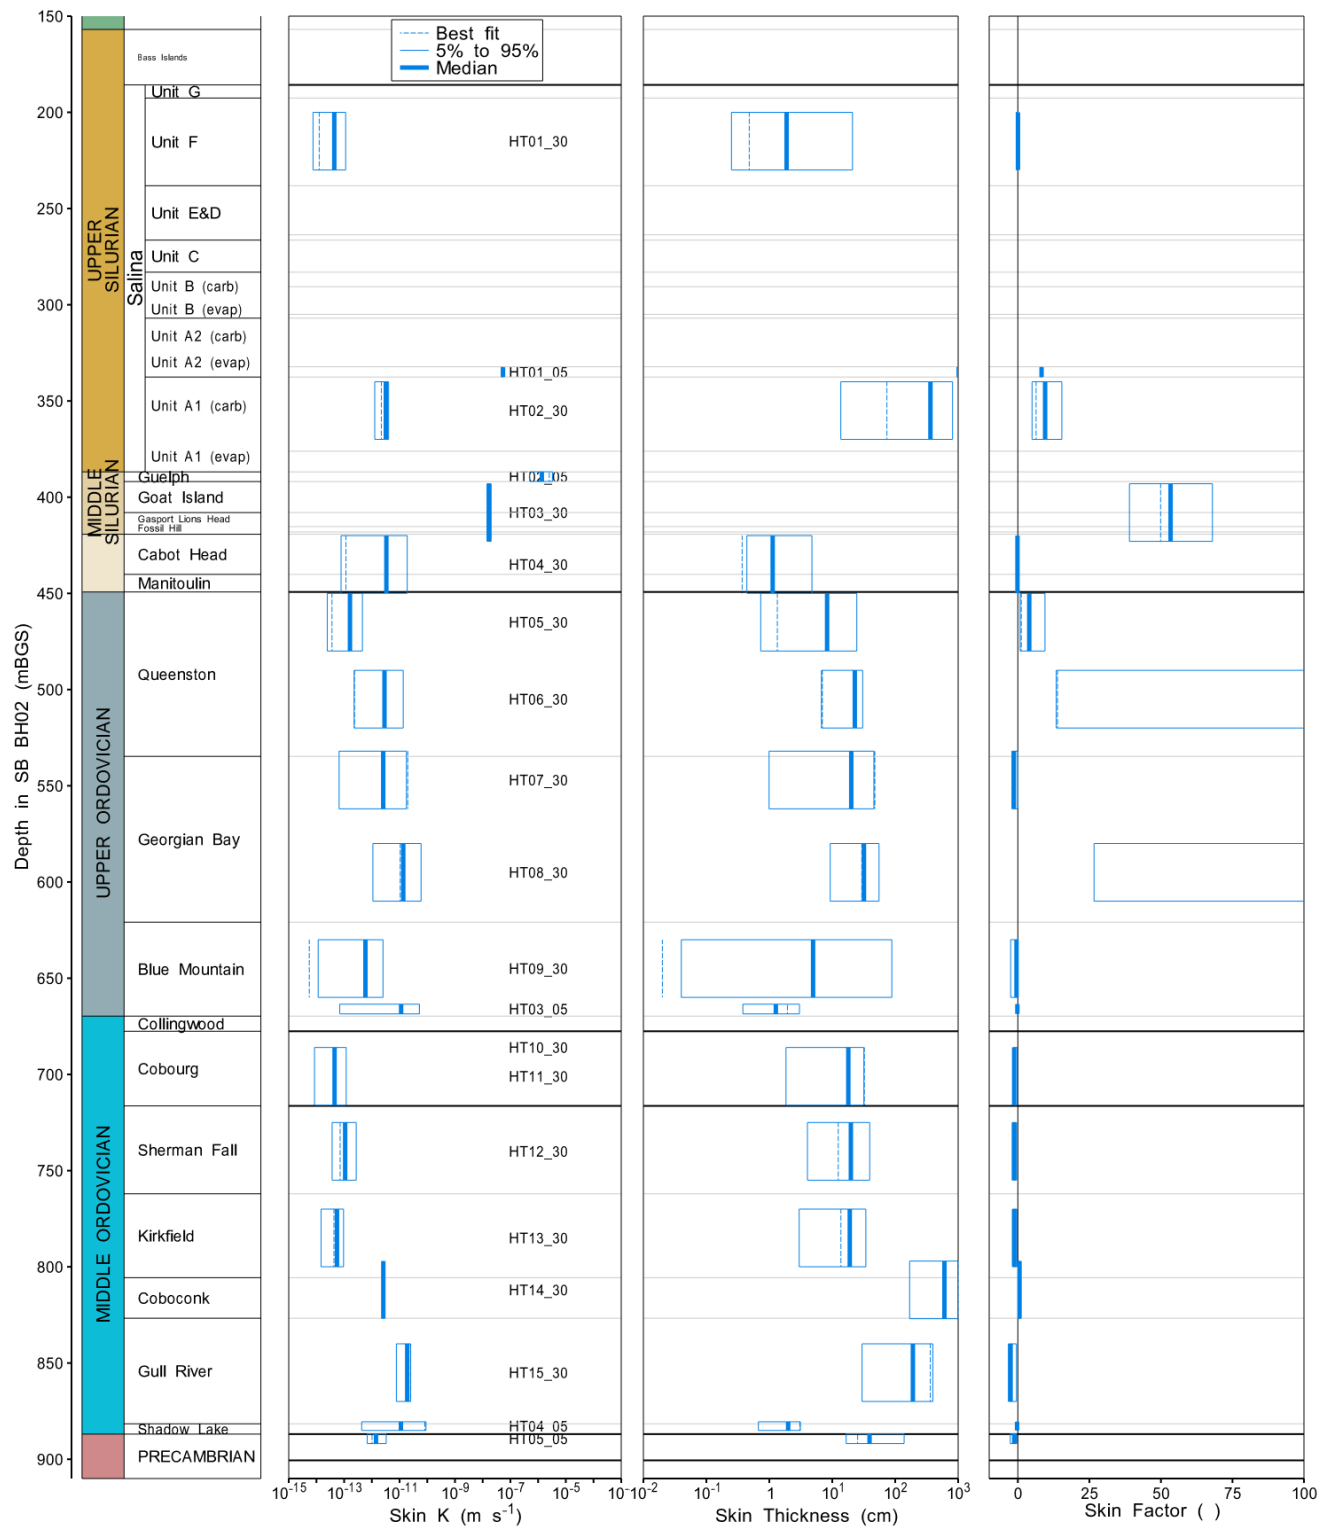

Figure 7.2 Skin Hydraulic Conductivity, Skin Thickness and Skin Factor.

Figure 7.3 Simulation Parameters: Test Zone Compressibility, Test Zone Radius, Borehole Fluid Density.

APPENDIX A

INDIVIDUAL TEST ANALYSES

A.1 HT01_05 Salina A2 Evaporite

The SB BH02 interval from 332.50 to 337.53 mBGS tested in HT01_05 covers the majority of the A2 Evaporite Unit of the Salina Group. Original testing plans called for a one day PI test. However, the test zone response to shut-in indicated relatively high hydraulic conductivity. A PI was attempted and it recovered completely in under 10 seconds. Subsequently, the tubing was swabbed and a SW test of one-day duration was performed. For analysis, the PI was treated as pressure history and only the SW was simulated. All figures presented in this chapter refer to the SW response.

A.1.1 Test Data Summary

Table A.1 and Figure A.1 provide a summary of test events and a plot of pressures measured while testing respectively.

Table A.1 - Summary of Test Events.

Event	Start Date & Time	Duration (days)	TZ Pressure (kPa)
Drilling intercept	22-01-03 14:47	153.13	3412
Shut-in	22-06-05 17:53	0.59	3409
Pulse injection	22-06-06 08:07	0.12	3459
Slug withdrawal	22-06-06 10:55	0.97	3177
Test end	22-06-07 10:13		3380

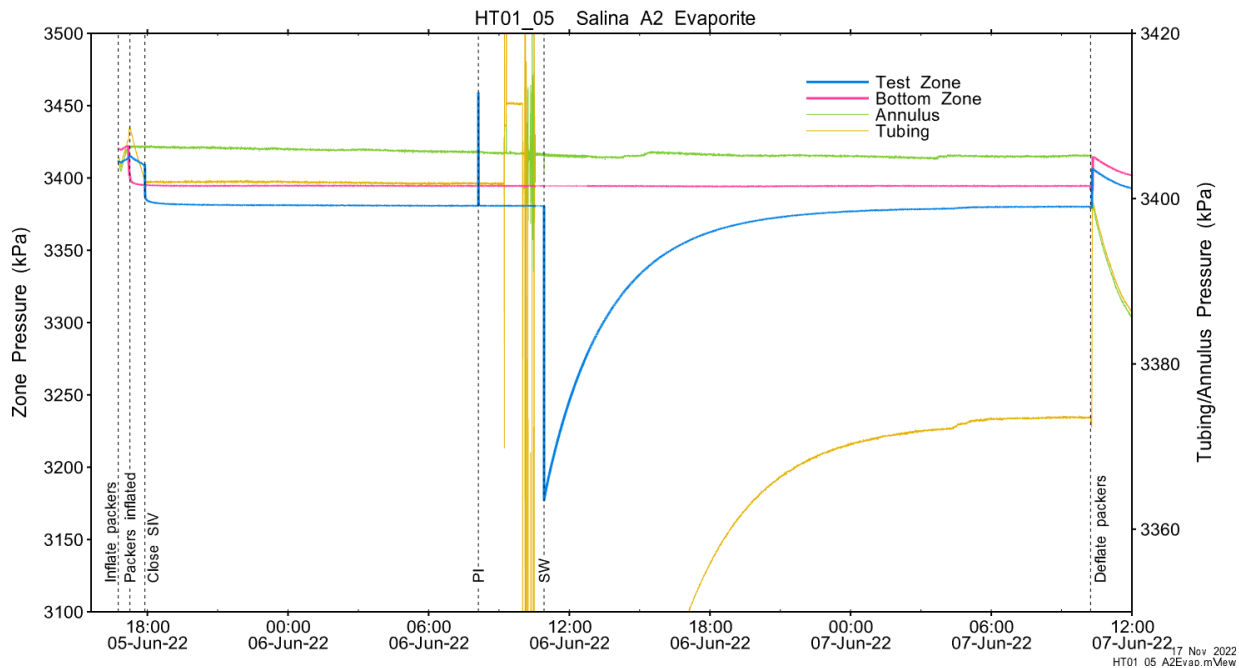

Figure A.1 - Test events and pressures.

A.1.2 Test Analyses

Table A.7 is a summary of test-specific input parameters used in the analyses, while Table A.8 presents the optimized parameters and allowed ranges. Perturbations were originally performed with wider conductivity range and a maximum 1000 cm skin thickness, however the skin thickness for the best fit was at the maximum skin thickness. Conductivity ranges were reduced and skin thickness increased to 2500 cm based on review of these initial results. Results from the second set also indicated a best-fit at the maximum thickness. A third set of permutations were run with maximum skin thickness of 100m.

Table A.2 – nSIGHTS Input Parameters.

Parameter	Value	Units
Test zone radius	6.74	cm
Tubing string radius	2.54	cm
Test zone length	5.03	m

Table A.3 – nSIGHTS Parameter Optimization Ranges.

Parameter	Minimum	Maximum	Units	Type
Formation hydraulic conductivity (K_f)	1E-10	1E-05	m/s	log
Formation pressure (P_f)	3000	4000	kPa	linear
Specific storage (S_s)	1E-08	1E-04	1/m	log
Skin hydraulic conductivity (K_s)	1E-10	1E-05	m/s	log
Skin thickness (t_s)	0.013	10000	cm	linear

Figure A.18 shows the measured test zone pressure record (with reduced data density for clarity) used in the analysis along with the best-fit simulation and parameter values. Figure A.19 presents the pre-test history, and Figure A.20 shows the Ramey B normalized best-fit pressure and pressure derivatives.

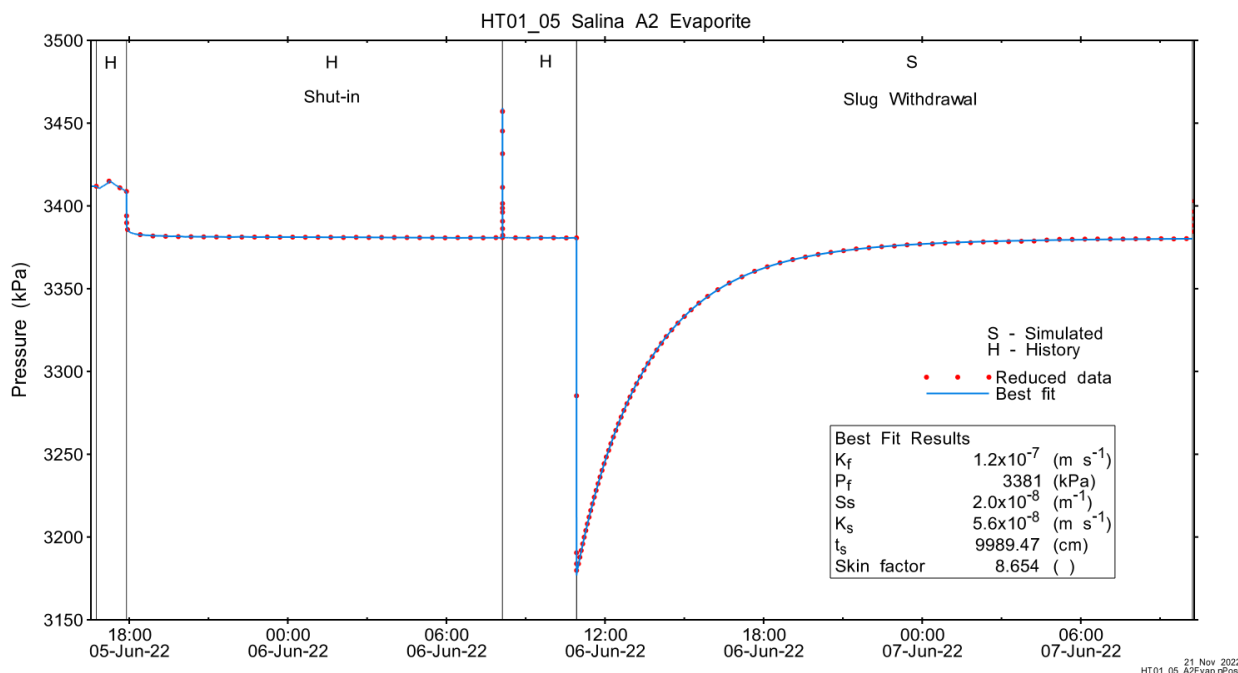

Figure A.2 - Annotated testing sequence showing best-fit simulation and parameter estimates.

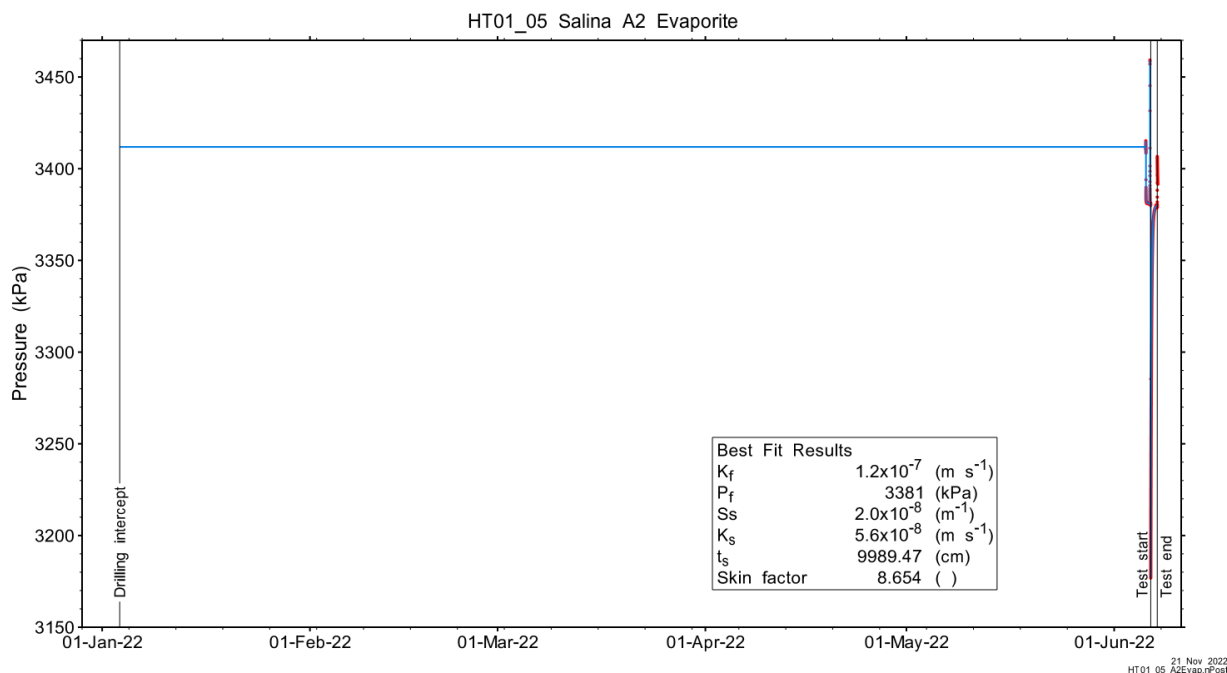

Figure A.3 - Annotated testing sequence showing pre-test history, best-fit simulation and parameter estimates.

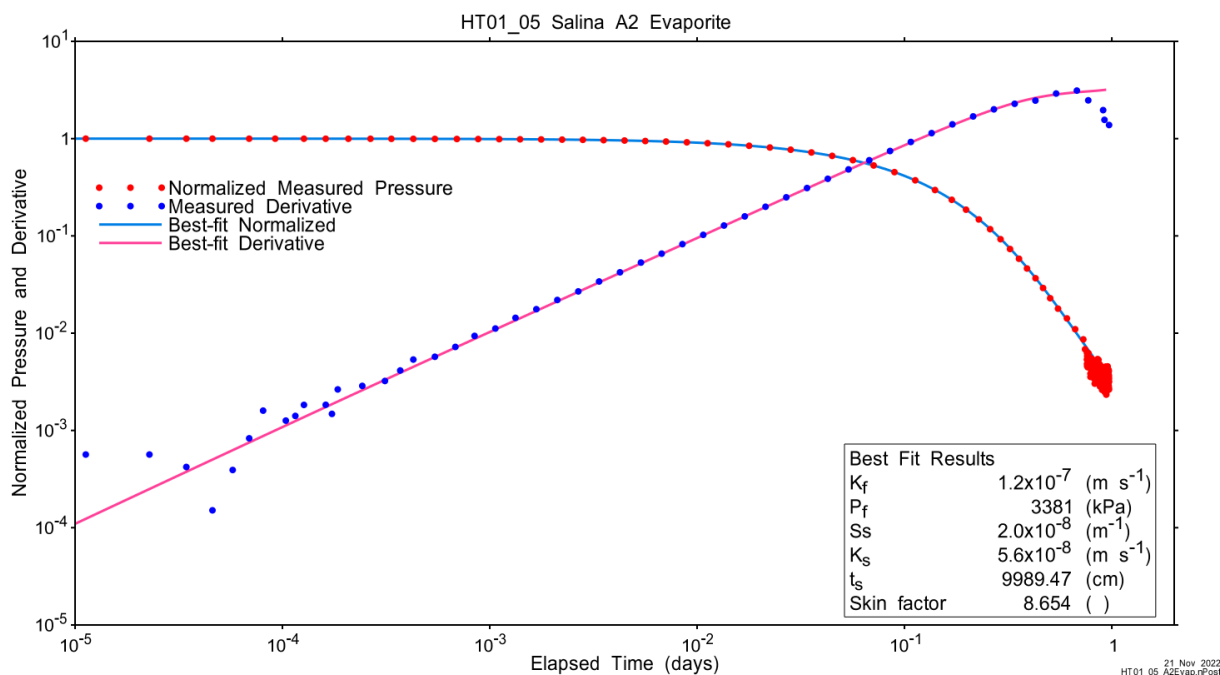

Figure A.4 - Log-log plot showing Ramey B and derivative response for best-fit simulation.

Figure A.21 shows the normalized parameter sensitivity response for the best fit. Sensitivity for fitting parameters is flat at the end of the test, indicating that test duration was sufficient.

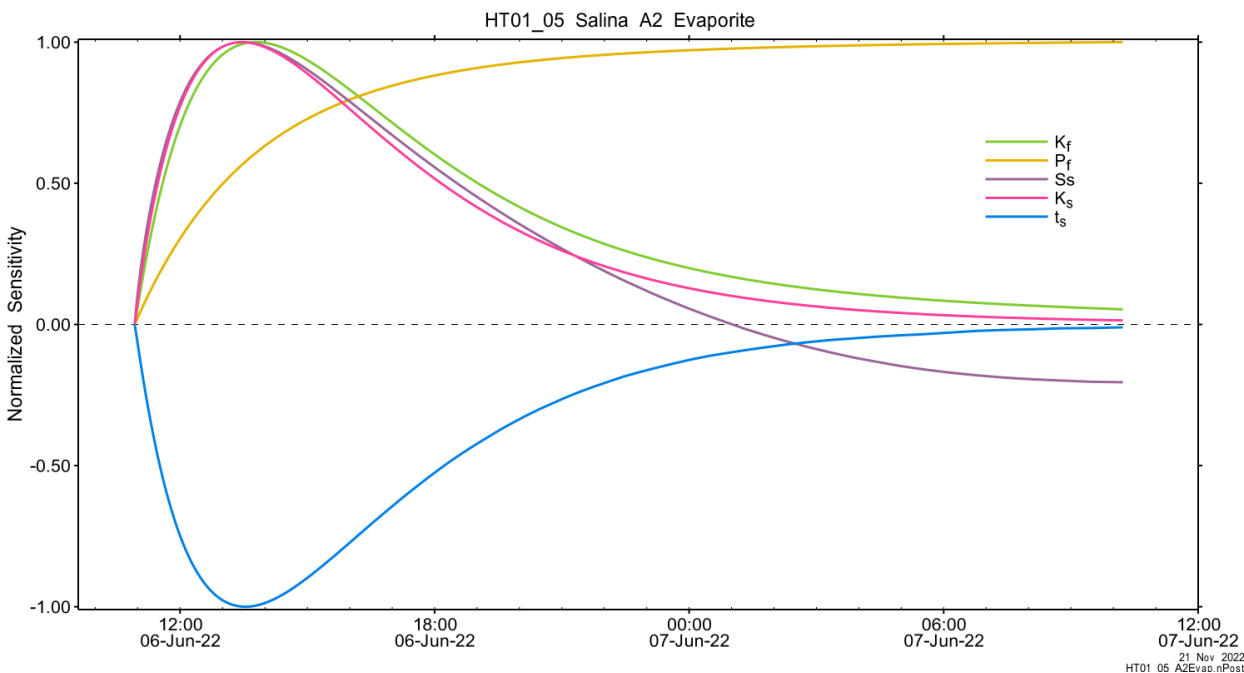

Figure A.5 - Normalized Jacobian for best-fit simulation.

A.1.3 Uncertainty Analyses

The CDF of normalized fit values for all converged simulations and the selected fit discriminant are shown in Figure A.22 and, in detail, in Figure A.7.

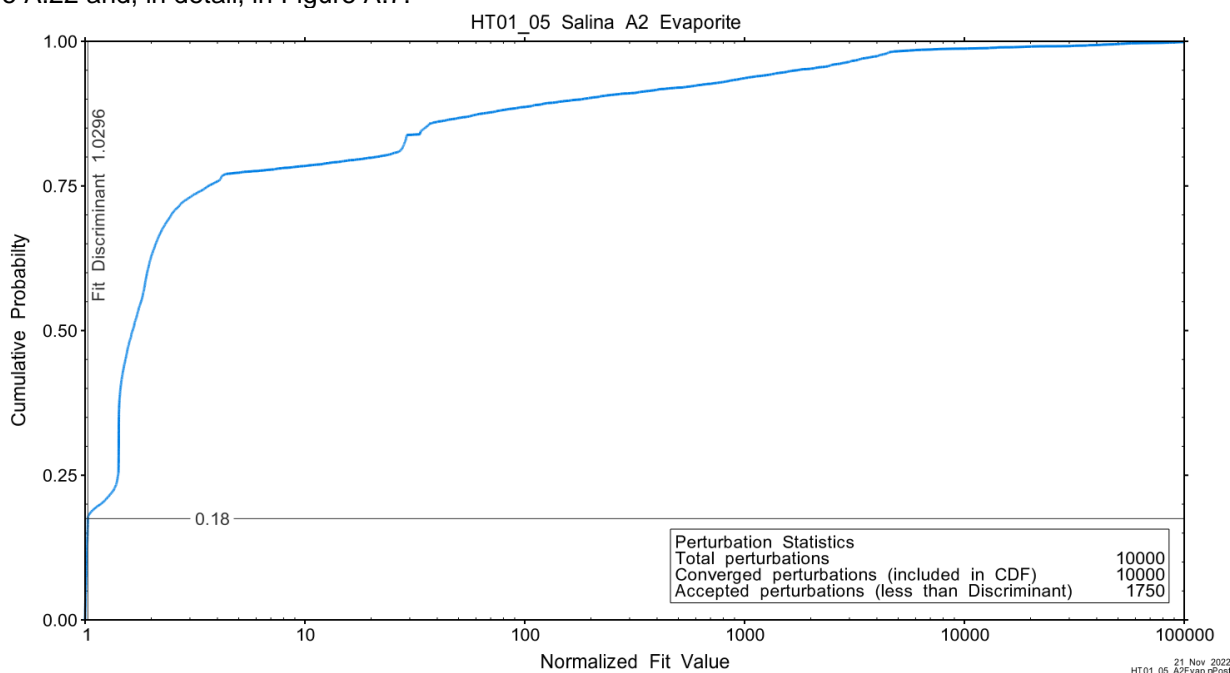

Figure A.6 - Fit value cumulative distribution function.

Figure A.7 – Detail of fit value cumulative distribution function.

Summary cross parameter scatter plots for selected formation and skin parameters are given in Figure A.24 and Figure A.25. The light pink dots on the figures are the initial parameter estimates, with red dots overlaying those initial parameter values that resulted in accepted optimization results. The grey dots are converged optimizations which did not meet the fit discriminant. Larger varying color symbols represent the fit value of accepted optimizations, with the blue values representing the best fit.

Figure A.8 - XY-scatter plot showing estimates of formation hydraulic conductivity (K_f) vs static formation pressure (P_f) (top panel) and specific storage (S_s) (bottom panel).

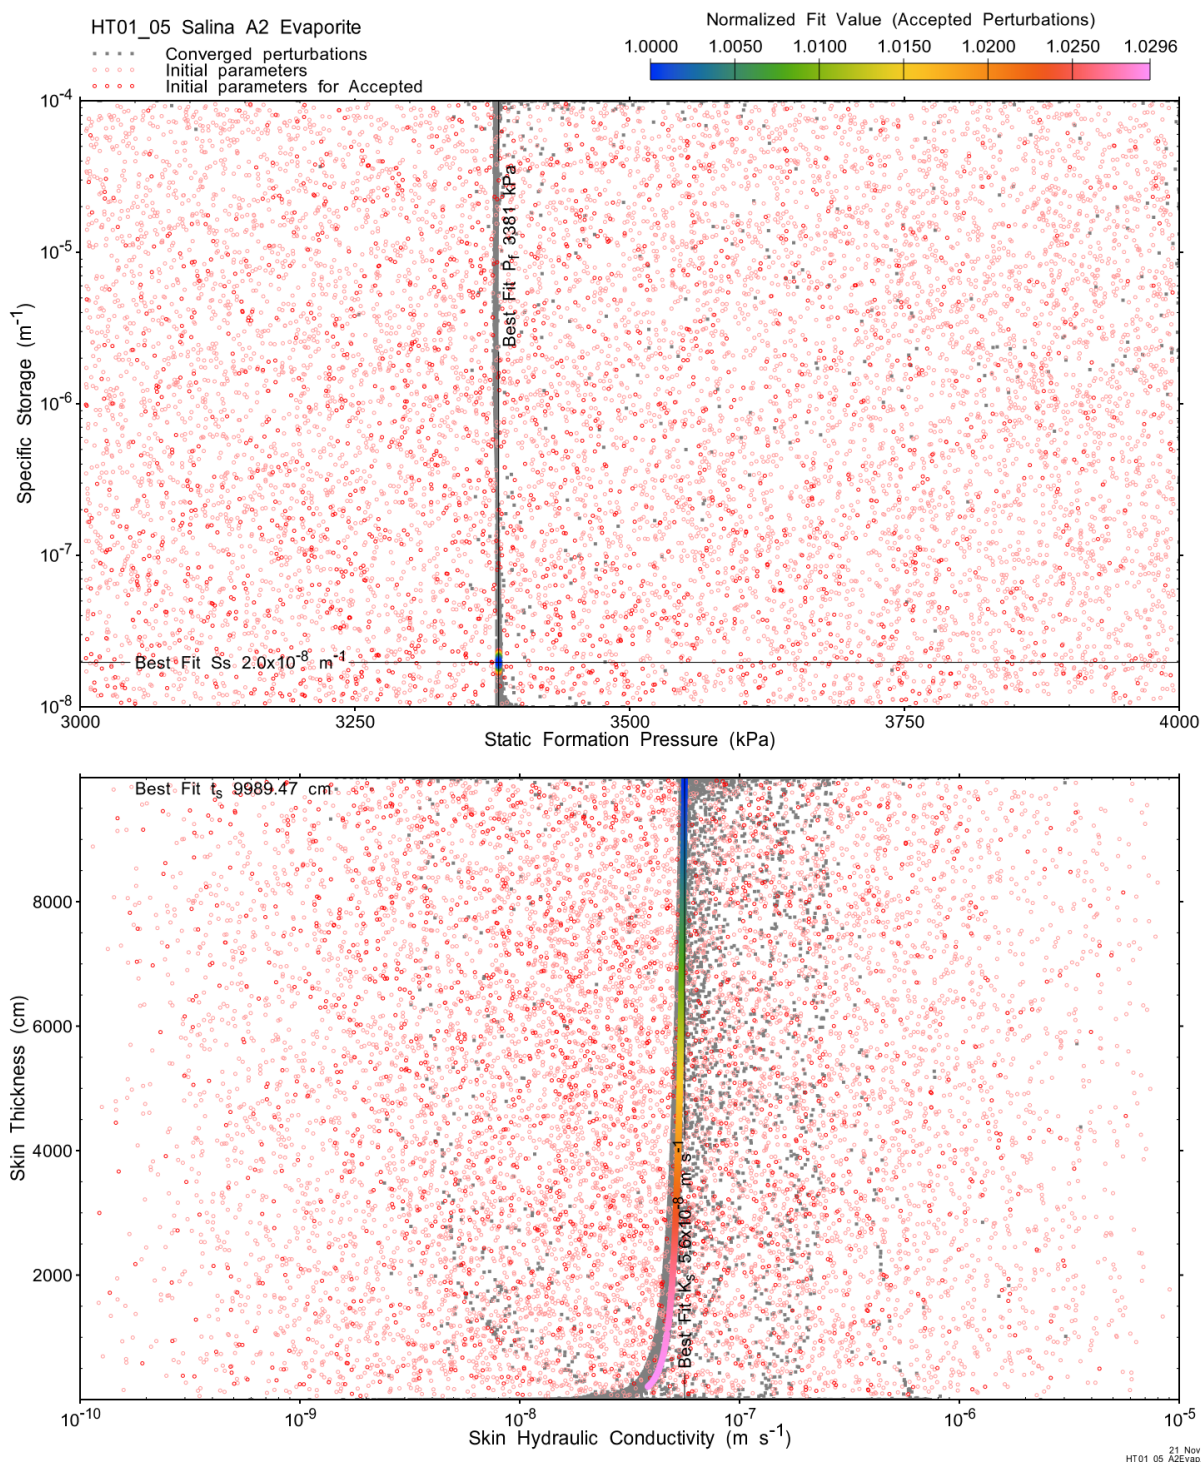

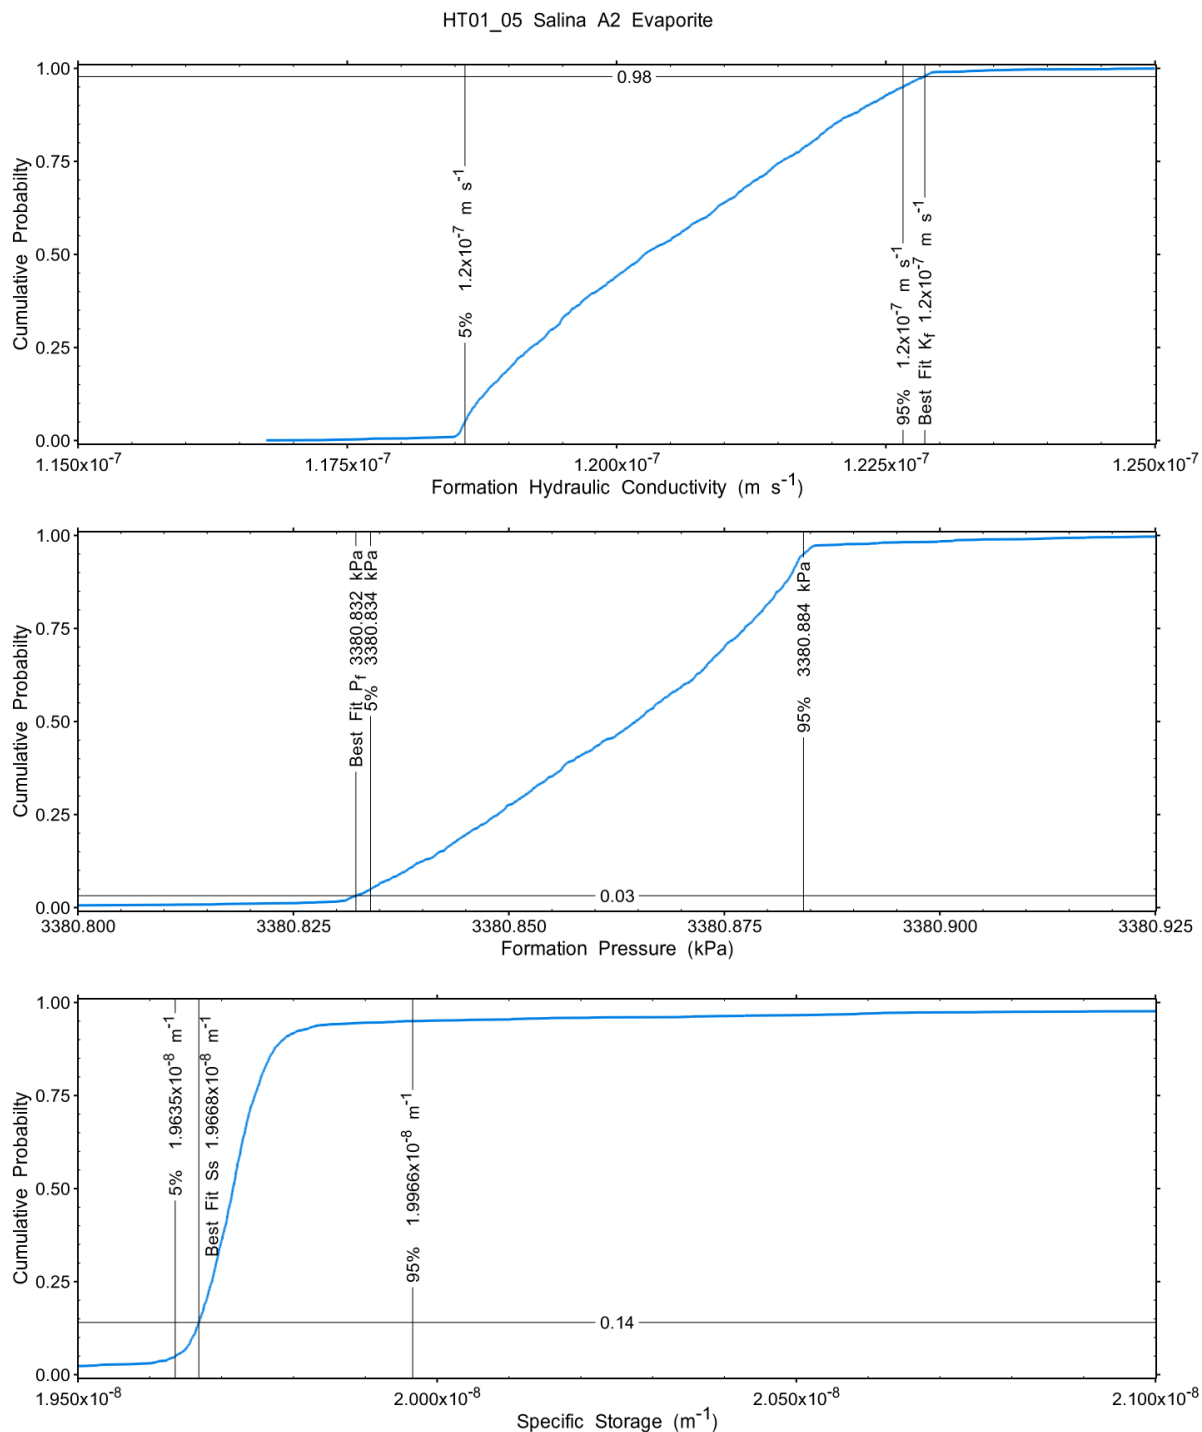

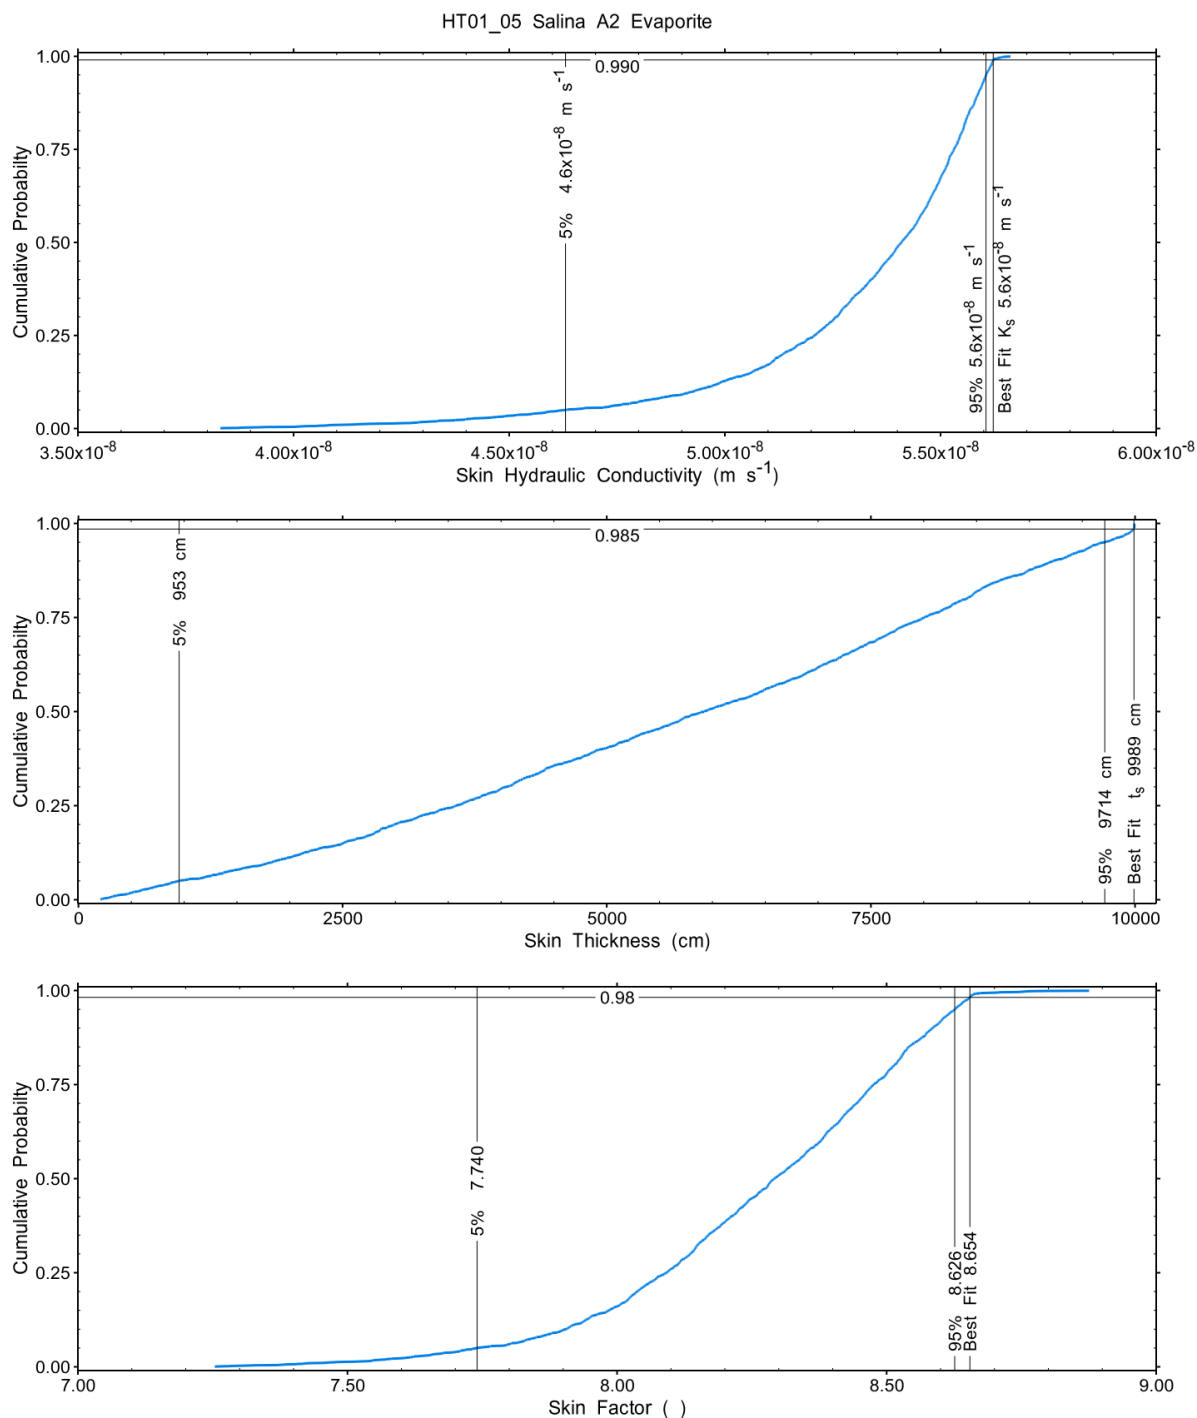

Figure A.9 - XY-scatter plot showing estimates of static formation pressure (P_i) vs specific storage (S_s) (top panel) and skin hydraulic conductivity (K_s) vs skin thickness (t_s) (bottom panel).

Confidence limits and median values are determined from the CDF of accepted optimization results (i.e. the varying color values in the above figures), with best fit value, 5% and 95% confidence indicated on Figure A.26 and Figure A.27.

HT01_05 A2Evap.nPost

Figure A.10 – Cumulative distribution functions and parameter limits for formation hydraulic conductivity (K_f) (top panel), static formation pressure (P_f) (middle panel) and specific storage (S_s) (bottom panel).

21 Nov 2022
HT01_05 A2Evaporite

Figure A.11 – Cumulative distribution functions and parameter limits for skin hydraulic conductivity (K_s) (top panel), skin thickness (t_s) (middle panel) and skin factor (s) (bottom panel).

A summary of perturbation results is presented in Figure A.28, with Ramey-processed perturbations in Figure A.13. Those perturbations (1411 of 10,000) with all parameters within the 5% and 95% range present an excellent fit to the measured test zone data.

Figure A.12 – Perturbation results – all converged, accepted, and within 5% to 95% for all parameters.

Figure A.13 – Log-log plot showing Ramey B and derivative response for all converged optimizations and those within 5% to 95% for all parameters.

A summary of best-fit and parameter ranges is given in Table A.9.

Table A.4 - Summary of the HT01_05 parameter estimates.

Parameter	Best Fit	5%	Median	95%
K_f (m/s)	1.2E-07	1.2E-07	1.2E-07	1.2E-07
P_f (kPa)	3381	3381	3381	3381
S_s (1/m)	2.0E-08	2.0E-08	2.0E-08	2.0E-08

A.2 HT02_05 Guelph

The SB BH02 interval from 386.80 to 391.83 mBGS tested in HT02_05 covers nearly the entirety of the Guelph Formation. A SW test of one-day duration was planned. However, the unit was very permeable and complete recovery was obtained within 20 hours, at which time the test was terminated.

A.2.1 Test Data Summary

Table A.6 and Figure A.1 provide a summary of test events and a plot of pressures measured while testing respectively.

Table A.6 - Summary of Test Events.

Event	Start Date & Time	Duration (days)	TZ Pressure (kPa)
Drilling intercept	22-01-04 23:22	153.64	3987
Shut-in	22-06-07 14:42	0.84	3976
Slug withdrawal	22-06-08 10:59	0.88	3691
Test end	22-06-09 08:08		3978

Figure A.17 - Test events and pressures.

A.2.2 Test Analyses

Table A.7 is a summary of test-specific input parameters used in the analyses, while Table A.8 presents the optimized parameters and allowed ranges. Perturbations were originally performed with wider conductivity and formation pressure ranges and a maximum 2500 cm skin thickness. Conductivity ranges were modified and skin thickness increased to 10000 cm based on review of initial results.

Test zone radius	6.54	cm
Tubing string radius	2.54	cm
Test zone length	5.03	m

Table A.8 – nSIGHTS Parameter Optimization Ranges.

Parameter	Minimum	Maximum	Units	Type
Formation hydraulic conductivity (K_f)	1E-08	1E-02	m/s	log
Formation pressure (P_f)	3900	4000	kPa	linear
Specific storage (S_s)	1E-08	1E-04	1/m	log
Skin hydraulic conductivity (K_s)	1E-08	1E-02	m/s	log
Skin thickness (t_s)	0.013	10000	cm	linear

Figure A.18 shows the measured test zone pressure record (with reduced data density for clarity) used in the analysis along with the best-fit simulation and parameter values. Figure A.19 presents the pre-test history, and Figure A.20 shows the Ramey B normalized best-fit pressure and pressure derivatives.

Figure A.18 - Annotated testing sequence showing best-fit simulation and parameter estimates.

Figure A.19 - Annotated testing sequence showing pre-test history, best-fit simulation and parameter estimates.

Figure A.20 - Log-log plot showing Ramey B and derivative response for best-fit simulation.

Figure A.21 shows the normalized parameter sensitivity response for the best fit. Sensitivity for fitting parameters is flat at the end of the test, indicating that test duration was sufficient. Results are not sensitive to the specific storage coefficient

Figure A.21 - Normalized Jacobian for best-fit simulation.

A.2.3 Uncertainty Analyses

The CDF of normalized fit values for all converged simulations and the selected fit discriminant are shown in Figure A.22 and, in detail, in Figure A.23 .

Figure A.22 - Fit value cumulative distribution function.

Figure A.23 – Detail of fit value cumulative distribution function.

Summary cross parameter scatter plots for selected formation and skin parameters are given in Figure A.24 and Figure A.25. The light pink dots on the figures are the initial parameter estimates, with red dots overlaying those initial parameter values that resulted in accepted optimization results. The grey dots are converged optimizations which did not meet the fit discriminant. Larger varying color symbols represent the fit value of accepted optimizations, with the blue values representing the best fit.

A.6 HT01_30 Salina F

The SB BH02 interval from 200.00 to 229.96 mBGS tested in HT01_30 includes the majority of the F Unit of the Salina Group. A PI test with a duration of one day was conducted.

A.6.1 Test Data Summary

Table A.6 and Figure A.1 provide a summary of test events and a plot of pressures measured while testing respectively.

Table A.26 - Summary of Test Events.

Event	Start Date & Time	Duration (days)	TZ Pressure (kPa)
Drilling intercept	21-12-31 02:18	183.61	2085
Shut-in	22-07-02 16:52	0.66	2084
Pulse injection	22-07-03 08:37	1.02	2622
Test end	22-07-04 09:00		2290

Figure A.82 - Test events and pressures.

A.6.2 Test Analyses

Table A.7 is a summary of test-specific input parameters used in the analyses, while Table A.8 presents the optimized parameters and allowed ranges.

Table A.27 – nSIGHTS Input Parameters.

Parameter	Value	Units
Test zone radius	6.63	cm
Test zone compressibility	4.65E-10	1/Pa
Test zone length	29.96	m

Table A.28 – nSIGHTS Parameter Optimization Ranges.

Parameter	Minimum	Maximum	Units	Type
Formation hydraulic conductivity (K_f)	1E-15	1E-09	m/s	log
Formation pressure (P_f)	0	2500	kPa	linear
Specific storage (S_s)	1E-08	1E-04	1/m	log
Skin hydraulic conductivity (K_s)	1E-15	1E-09	m/s	log
Skin thickness (t_s)	0.013	2500	cm	linear

Figure A.18 shows the measured test zone pressure record (with reduced data density for clarity) used in the analysis along with the best-fit simulation and parameter values. Figure A.19 presents the pre-test history, and Figure A.20 shows the Ramey B normalized best-fit pressure and pressure derivatives.

Figure A.83 - Annotated testing sequence showing best-fit simulation and parameter estimates.

Figure A.84 - Annotated HT01_30 testing sequence showing pre-test history, best-fit simulation and parameter estimates.

Figure A.85 - Log-log plot showing Ramey B and derivative response for best-fit simulation.

Figure A.21 shows the normalized parameter sensitivity response for the best fit. Sensitivity for K_f and P_f were still increasing at the end of the test, indicating that an increased test duration may have yielded improved estimates of these parameters.

Figure A.86 - Normalized Jacobian for best-fit simulation.

A.6.3 Uncertainty Analyses

An initial uncertainty analyses was conducted with 10,000 perturbations. Results revealed a very small and poorly defined (less than 10 perturbations met fit criteria) global minimum. The parameter ranges were tightened slightly and a 50,000 perturbation analysis conducted, results of which are presented here. The CDF of normalized fit values for all converged simulations and the selected fit discriminant are shown in Figure A.22 and Figure A.88.

Figure A.87 - Fit value cumulative distribution function.

Figure A.88 - Fit value cumulative distribution function (detail).

Summary cross parameter scatter plots for selected formation and skin parameters are given in Figure A.24 and Figure A.25. The light pink dots on the figures are the initial parameter estimates, with red dots overlaying those initial parameter values that resulted in accepted optimization results. The grey dots are converged optimizations which did not meet the fit discriminant. Larger varying color symbols represent the fit value of accepted optimizations, with the blue values representing the best fit.

Figure A.89 - XY-scatter plot showing estimates of formation hydraulic conductivity (K_f) vs static formation pressure (P_f) (top panel) and specific storage (S_s) (bottom panel).

Figure A.90 - XY-scatter plot showing estimates of static formation pressure (P_f) vs specific storage (S_s) (top panel) and skin hydraulic conductivity (K_s) vs skin thickness (t_s) (bottom panel).

Confidence limits and median values are determined from the CDF of accepted optimization results (i.e. the varying color values in the above figures), with best fit value, 5% and 95% confidence indicated on Figure A.26 and Figure A.27.

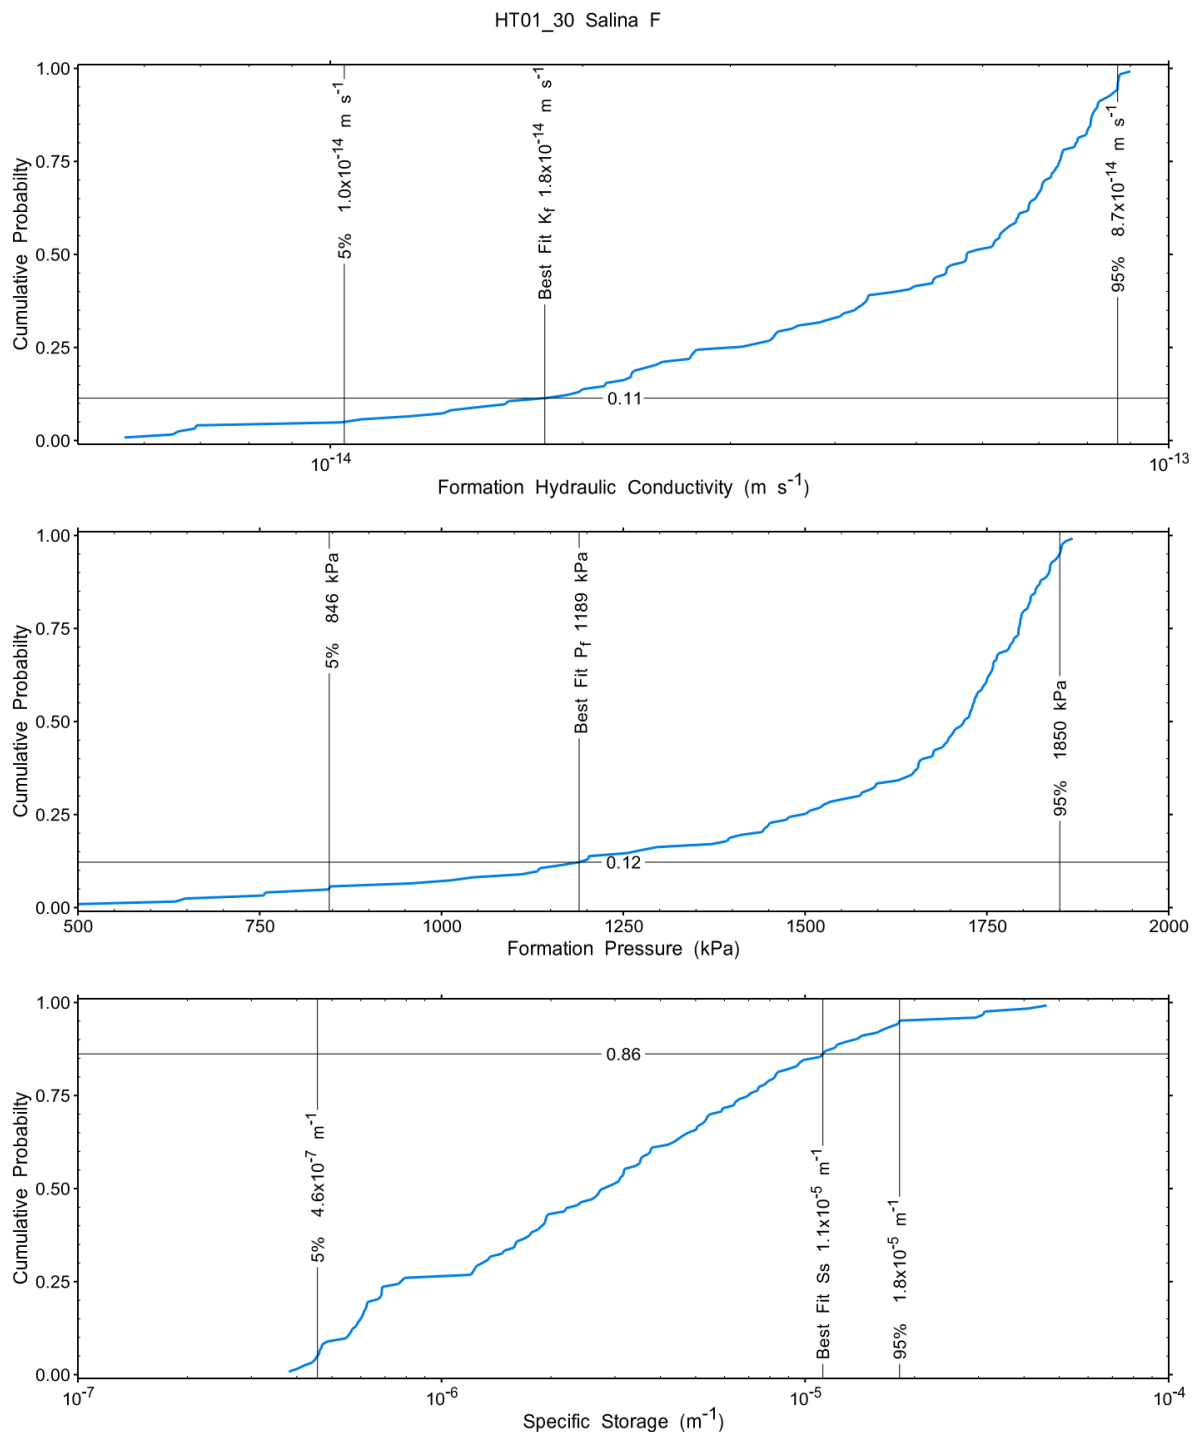

Figure A.91 – Cumulative distribution functions and parameter limits for formation hydraulic conductivity (K_f) (top panel), static formation pressure (P_f) (middle panel) and specific storage (S_s) (bottom panel).

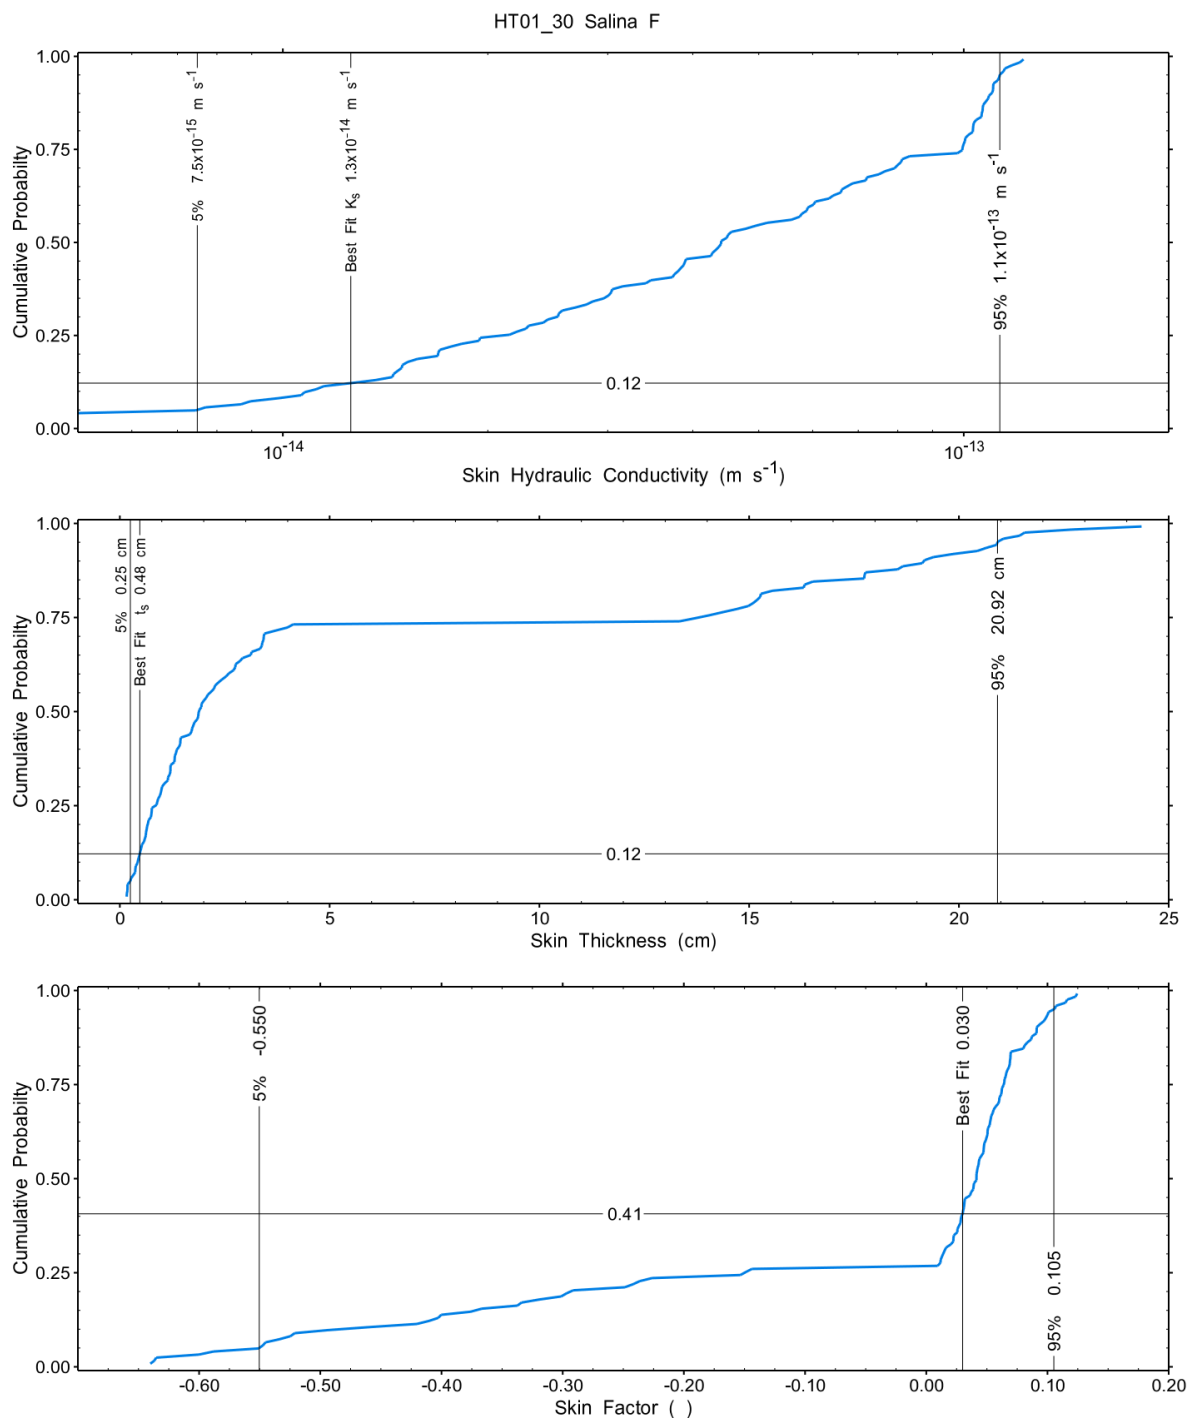

Figure A.92 – Cumulative distribution functions and parameter limits for skin hydraulic conductivity (K_s) (top panel), skin thickness (t_s) (middle panel) and skin factor (s) (bottom panel).

A summary of perturbation results is presented in Figure A.28, with Ramey-processed perturbations in Figure 12. Those perturbations (2548 of 10,000) with all parameters within the 5% and 95% range present a very good fit to the measured test zone data.

Figure A.93 – Perturbation results – all converged, accepted, and within 5% to 95% for all parameters.

Figure A.94 – Log-log plot showing Ramey B and derivative response for all converged optimizations and those within 5% to 95% for all parameters.

A summary of best-fit and parameter ranges is given in Table A.9.

Table A.29 - Summary of the HT01_30 parameter estimates.

Parameter	Best Fit	5%	Median	95%
K_f (m/s)	1.8E-14	1.0E-14	5.7E-14	8.7E-14
P_f (kPa)	1189	846	1718	1850
S_s (1/m)	1.1E-05	4.6E-07	2.8E-06	1.8E-05
K_s (m/s)	1.3E-14	7.5E-15	4.4E-14	1.1E-13
t_s (cm)	0.48	0.25	1.88	20.92
s (-)	0.030	-0.550	0.041	0.105

Parameter correlations for all perturbations with all parameters within the 5% to 95% limits are given in Table A.5.

Table A.30 – Pearson cross-correlations of 5% to 95% parameters

	$\text{Log}(K_f)$	P_f	$\text{Log}(S_s)$	$\text{Log}(K_s)$	t_s	s
$\text{Log}(K_f)$	1.000	0.961	-0.919	0.969	0.579	-0.409
P_f	0.961	1.000	-0.810	0.886	0.466	-0.280
$\text{Log}(S_s)$	-0.919	-0.810	1.000	-0.988	-0.832	0.723
$\text{Log}(K_s)$	0.969	0.886	-0.988	1.000	0.750	-0.615
t_s	0.579	0.466	-0.832	0.750	1.000	-0.969

A.7 HT02_30 Salina A1

The SB BH02 interval from 340.00 to 369.96 mBGS tested in HT02_30 includes the majority of the A1 Carbonate Unit of the Salina Group. A PI test with a duration of one day was conducted.

A.7.1 Test Data Summary

Table A.6 and Figure A.1 provide a summary of test events and a plot of pressures measured while testing respectively. Previous testing of this unit in other boreholes indicated the potential for a high permeability response. Accordingly, the tubing was swabbed and the test set up for an initial SW (Attempted SW on Figure A.1). After initiating the SW, the response was monitored for approximately 90 minutes. There was virtually no recovery, so the shut-valve was closed and the PI initiated 15 minutes later.

Table A.31 - Summary of Test Events.

Event	Start Date & Time	Duration (days)	TZ Pressure (kPa)
Drilling intercept	22-01-04 06:03	186.32	3585
Shut-in	22-07-09 13:37	0.86	3584
Pulse injection	22-07-10 10:21	1.01	3853
Test end	22-07-11 10:31		3464

Figure A.98 - Test events and pressures.

A.7.2 Test Analyses

Table A.7 is a summary of test-specific input parameters used in the analyses, while Table A.8 presents the optimized parameters and allowed ranges.

Table A.32 – nSIGHTS Input Parameters.

Parameter	Value	Units
Test zone radius	6.73	cm
Test zone compressibility	4.13E-10	1/Pa
Test zone length	29.96	m

Table A.33 – nSIGHTS Parameter Optimization Ranges.

Parameter	Minimum	Maximum	Units	Type
Formation hydraulic conductivity (K_f)	1E-15	1E-09	m/s	log
Formation pressure (P_f)	1000	5000	kPa	linear
Specific storage (S_s)	1E-08	1E-04	1/m	log
Skin hydraulic conductivity (K_s)	1E-15	1E-09	m/s	log
Skin thickness (t_s)	0.013	1000	cm	linear

Figure A.18 shows the measured test zone pressure record (with reduced data density for clarity) used in the analysis along with the best-fit simulation and parameter values. Figure A.19 presents the pre-test history, and Figure A.20 shows the Ramey B normalized best-fit pressure and pressure derivatives.

Figure A.99 - Annotated testing sequence showing best-fit simulation and parameter estimates.

Figure A.100 - Annotated HT02_30 testing sequence showing pre-test history, best-fit simulation and parameter estimates.

Figure A.101 - Log-log plot showing Ramey B and derivative response for best-fit simulation.

Figure A.21 shows the normalized parameter sensitivity response for the best fit. Sensitivity for all fitting parameters was relatively constant by the end of the test, indicating that the test duration was sufficient for well-constrained parameter estimation.

Figure A.102 - Normalized Jacobian for best-fit simulation.

A.7.3 Uncertainty Analyses

The CDF of normalized fit values for all converged simulations and the selected fit discriminant are shown in Figure A.22.

Figure A.103 - Fit value cumulative distribution function.

Summary cross parameter scatter plots for selected formation and skin parameters are given in Figure A.24 and Figure A.25. The light pink dots on the figures are the initial parameter estimates, with red dots overlaying those initial parameter values that resulted in accepted optimization results. The grey dots are converged optimizations which did not meet the fit discriminant. Larger varying color symbols represent the fit value of accepted optimizations, with the blue values representing the best fit.

A.8 HT03_30 Goat Island

The SB BH02 interval from 393.00 to 422.96 mBGS tested in HT03_30 includes the Goat Island, Gasport, Lions Head, and Fossil Hill Formations, as well as 3m of the upper Cabot Head Formation. A PI test was originally intended for the interval, however after the test zone was shut-in, the rapid equilibration of the test zone indicated relatively high permeability. Consequently, the tubing was swabbed and a one day duration SW test was conducted.

A.8.1 Test Data Summary

Table A.6 and Figure A.1 provide a summary of test events and a plot of pressures measured while testing respectively.

Table A.36 - Summary of Test Events.

A.10 HT05_30 Upper Queenston

The SB BH02 interval from 450.00 to 479.96 mBGS tested in HT05_30 consists of the upper 30m of the Queenston Formation. A single PI test of two days duration was conducted.

A.10.1 Test Data Summary

Table A.6 and Figure A.1 provide a summary of test events and a plot of pressures measured while testing respectively.

Table A.46 - Summary of Test Events.

Event	Start Date & Time	Duration (days)	TZ Pressure (kPa)
Drilling intercept	22-01-06 00:39	190.45	4654
Shut-in	22-07-15 11:30	0.86	4667
Pulse injection	22-07-16 08:06	2.00	5122
Test end	22-07-18 08:09		4962

Figure A.145 - Test events and pressures.

A.10.2 Test Analyses

Table A.7 is a summary of test-specific input parameters used in the analyses, while Table A.8 presents the optimized parameters and allowed ranges.

Table A.47 – nSIGHTS Input Parameters.

Parameter	Value	Units
Test zone radius	7.45	cm
Test zone compressibility	4.58E-10	1/Pa
Test zone length	29.96	m

Table A.48 – nSIGHTS Parameter Optimization Ranges.

Parameter	Minimum	Maximum	Units	Type
Formation hydraulic conductivity (K_f)	1E-16	1E-09	m/s	log
Formation pressure (P_f)	3000	9000	kPa	linear
Specific storage (S_s)	1E-08	1E-04	1/m	log
Skin hydraulic conductivity (K_s)	1E-16	1E-09	m/s	log
Skin thickness (t_s)	0.013	1000	cm	linear

Figure A.18 shows the measured test zone pressure record (with reduced data density for clarity) used in the analysis along with the best-fit simulation and parameter values. Figure A.19 presents the pre-test history, and Figure A.20 shows the Ramey B normalized best-fit pressure and pressure derivatives.

Figure A.146 - Annotated testing sequence showing best-fit simulation and parameter estimates.

Figure A.147 - Annotated HT05_30 testing sequence showing pre-test history, best-fit simulation and parameter estimates.

Figure A.148 - Log-log plot showing Ramey B and derivative response for best-fit simulation.

Figure A.21 shows the normalized parameter sensitivity response for the best fit. Sensitivity for all fitting parameters (except S_s) was rising at the end of the test, indicating that a longer test may have returned more precise results.

Figure A.149 - Normalized Jacobian for best-fit simulation.

A.10.3 Uncertainty Analyses

The CDF of normalized fit values for all converged simulations and the selected fit discriminant are shown in Figure A.22. The initial fit discriminant selected was somewhat higher (1.55), however, this resulted in inclusion of a local minimum (see Appendix plots). The fit value was adjusted downward to 1.25, at which point only the global minimum remained.

Figure A.150 - Fit value cumulative distribution function.

Summary cross parameter scatter plots for selected formation and skin parameters are given in Figure A.24 and Figure A.25. The light pink dots on the figures are the initial parameter estimates, with red dots overlaying those initial parameter values that resulted in accepted optimization results. The grey dots are converged optimizations which did not meet the fit discriminant. Larger varying color symbols represent the fit value of accepted optimizations, with the blue values representing the best fit.

Figure A.151 - XY-scatter plot showing estimates of formation hydraulic conductivity (K_f) vs static formation pressure (P_f) (top panel) and specific storage (S_s) (bottom panel).

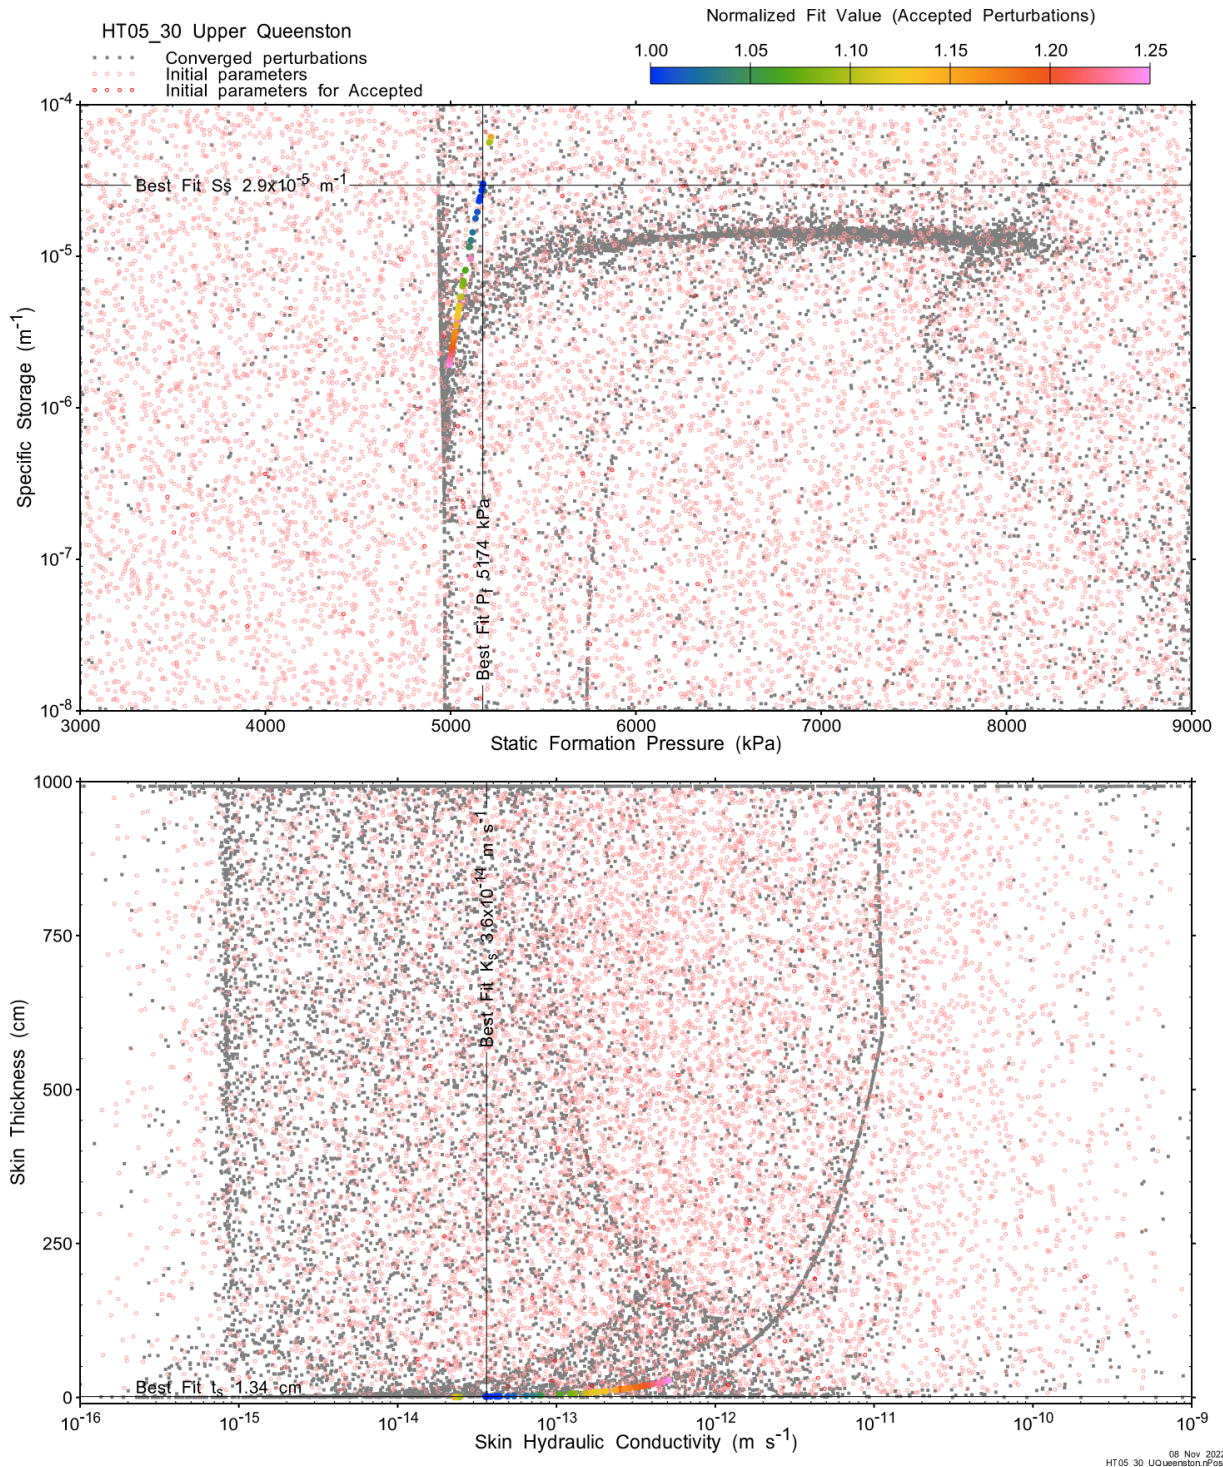

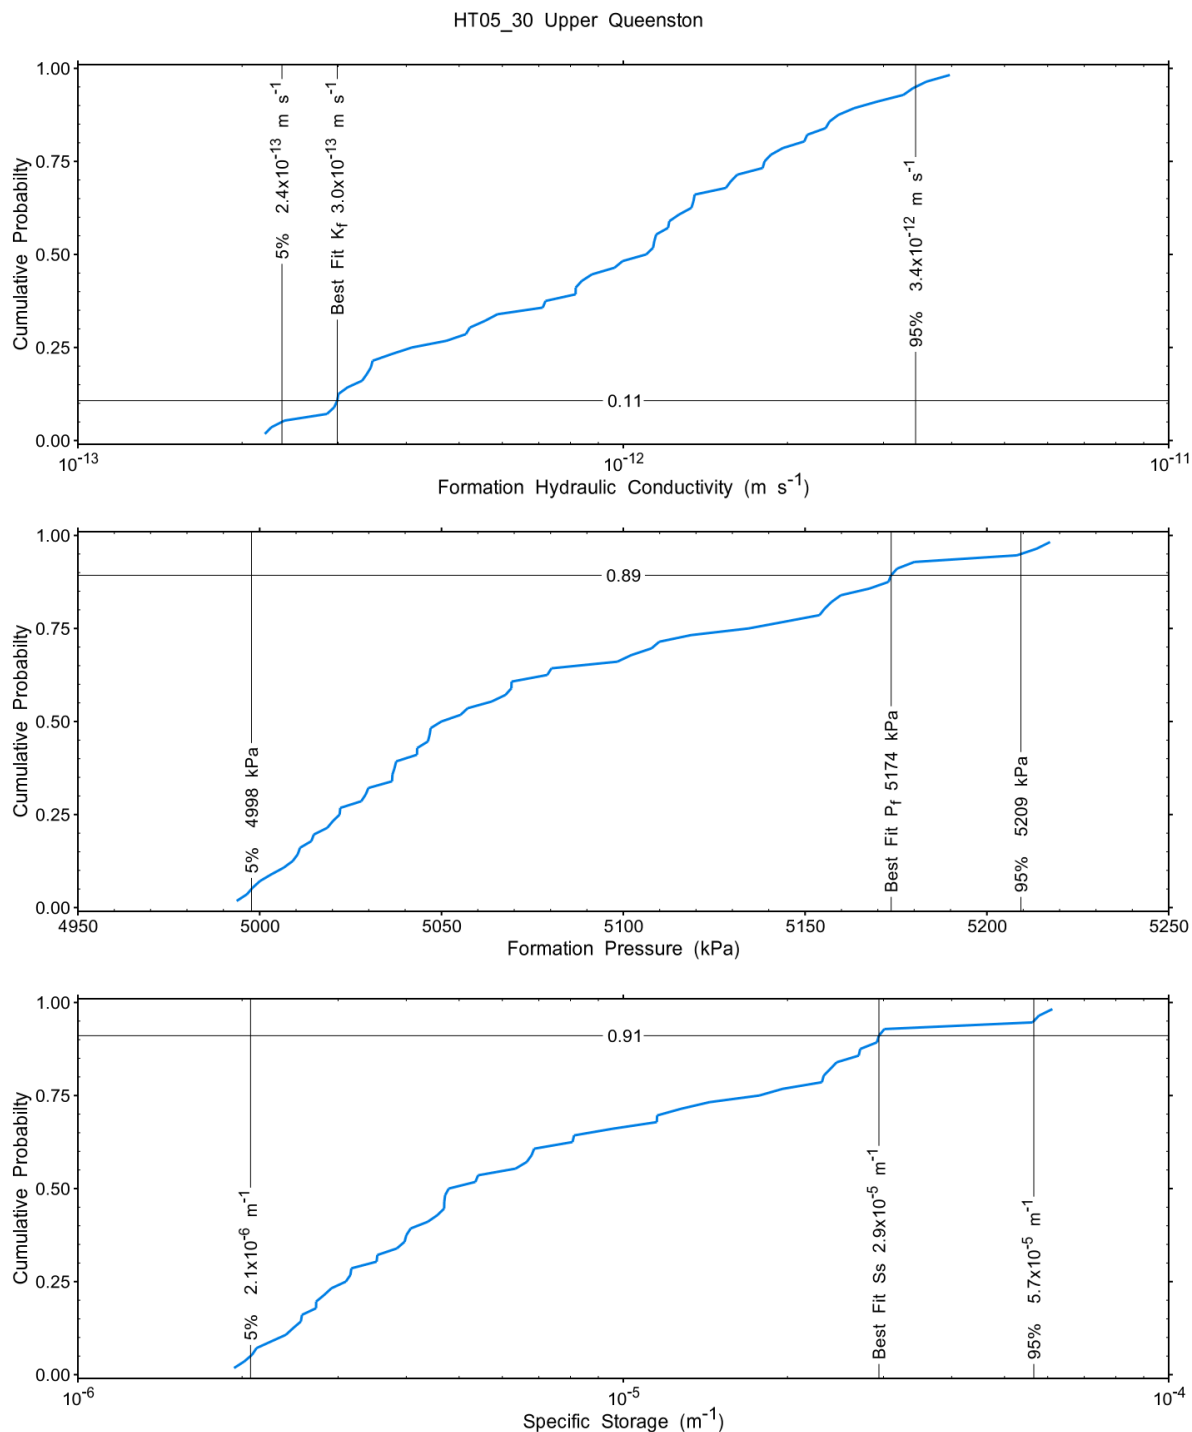

Figure A.152 - XY-scatter plot showing estimates of static formation pressure (P_i) vs specific storage (S_s) (top panel) and skin hydraulic conductivity (K_s) vs skin thickness (t_s) (bottom panel).

Confidence limits and median values are determined from the CDF of accepted optimization results (i.e. the varying color values in the above figures), with best fit value, 5% and 95% confidence indicated on Figure A.26 and Figure A.27.

A.14 HT09_30 Blue Mountain

The SB BH02 interval from 630.00 to 659.96 mBGS tested in HT09_30 covers the majority of the Blue Mountain Formation. A single PI test of two days duration was conducted.

A.14.1 Test Data Summary

Table A.6 and Figure A.1 provide a summary of test events and a plot of pressures measured while testing respectively.

Table A.66 - Summary of Test Events.

Event	Start Date & Time	Duration (days)	TZ Pressure (kPa)
Drilling intercept	22-03-11 10:47	143.21	6639
Shut-in	22-08-01 15:44	0.70	6705
Pulse injection	22-08-02 08:33	2.00	6840
Test end	22-08-04 08:32		6628

Figure A.208 - Test events and pressures.

A.14.2 Test Analyses

Table A.7 is a summary of test-specific input parameters used in the analyses, while Table A.8 presents the optimized parameters and allowed ranges. The specific storage parameter range was increased based on initial perturbation results.

Table A.67 – nSIGHTS Input Parameters.

Parameter	Value	Units
Test zone radius	6.49	cm
Test zone compressibility	1.30E-09	1/Pa
Test zone length	29.96	m

Table A.68 – nSIGHTS Parameter Optimization Ranges.

Parameter	Minimum	Maximum	Units	Type
Formation hydraulic conductivity (K_f)	1E-16	1E-08	m/s	log
Formation pressure (P_f)	2000	7000	kPa	linear
Specific storage (S_s)	1E-08	1E-03	1/m	log
Skin hydraulic conductivity (K_s)	1E-16	1E-08	m/s	log
Skin thickness (t_s)	0.013	500	cm	linear

Figure A.18 shows the measured test zone pressure record (with reduced data density for clarity) used in the analysis along with the best-fit simulation and parameter values. Figure A.19 presents the pre-test history, and Figure A.20 shows the Ramey B normalized best-fit pressure and pressure derivatives.

Figure A.209 - Annotated testing sequence showing best-fit simulation and parameter estimates.

Figure A.210 - Annotated testing sequence showing pre-test history, best-fit simulation and parameter estimates.

Figure A.211 - Log-log plot showing Ramey B and derivative response for best-fit simulation.

Figure A.21 shows the normalized parameter sensitivity response for the best fit. Sensitivity for most fitting parameters was increasing at the end of the test, indicating that lengthening the test may have improved the precision of the analysis.

Figure A.212 - Normalized Jacobian for best-fit simulation.

A.14.3 Uncertainty Analyses

The CDF of normalized fit values for all converged simulations and the selected fit discriminant are shown in Figure A.22.

Figure A.213 - Fit value cumulative distribution function.

Summary cross parameter scatter plots for selected formation and skin parameters are given in Figure A.24 and Figure A.25. The light pink dots on the figures are the initial parameter estimates, with red dots overlaying those initial parameter values that resulted in accepted optimization results. The grey dots are converged optimizations which did not meet the fit discriminant. Larger varying color symbols represent the fit value of accepted optimizations, with the blue values representing the best fit.

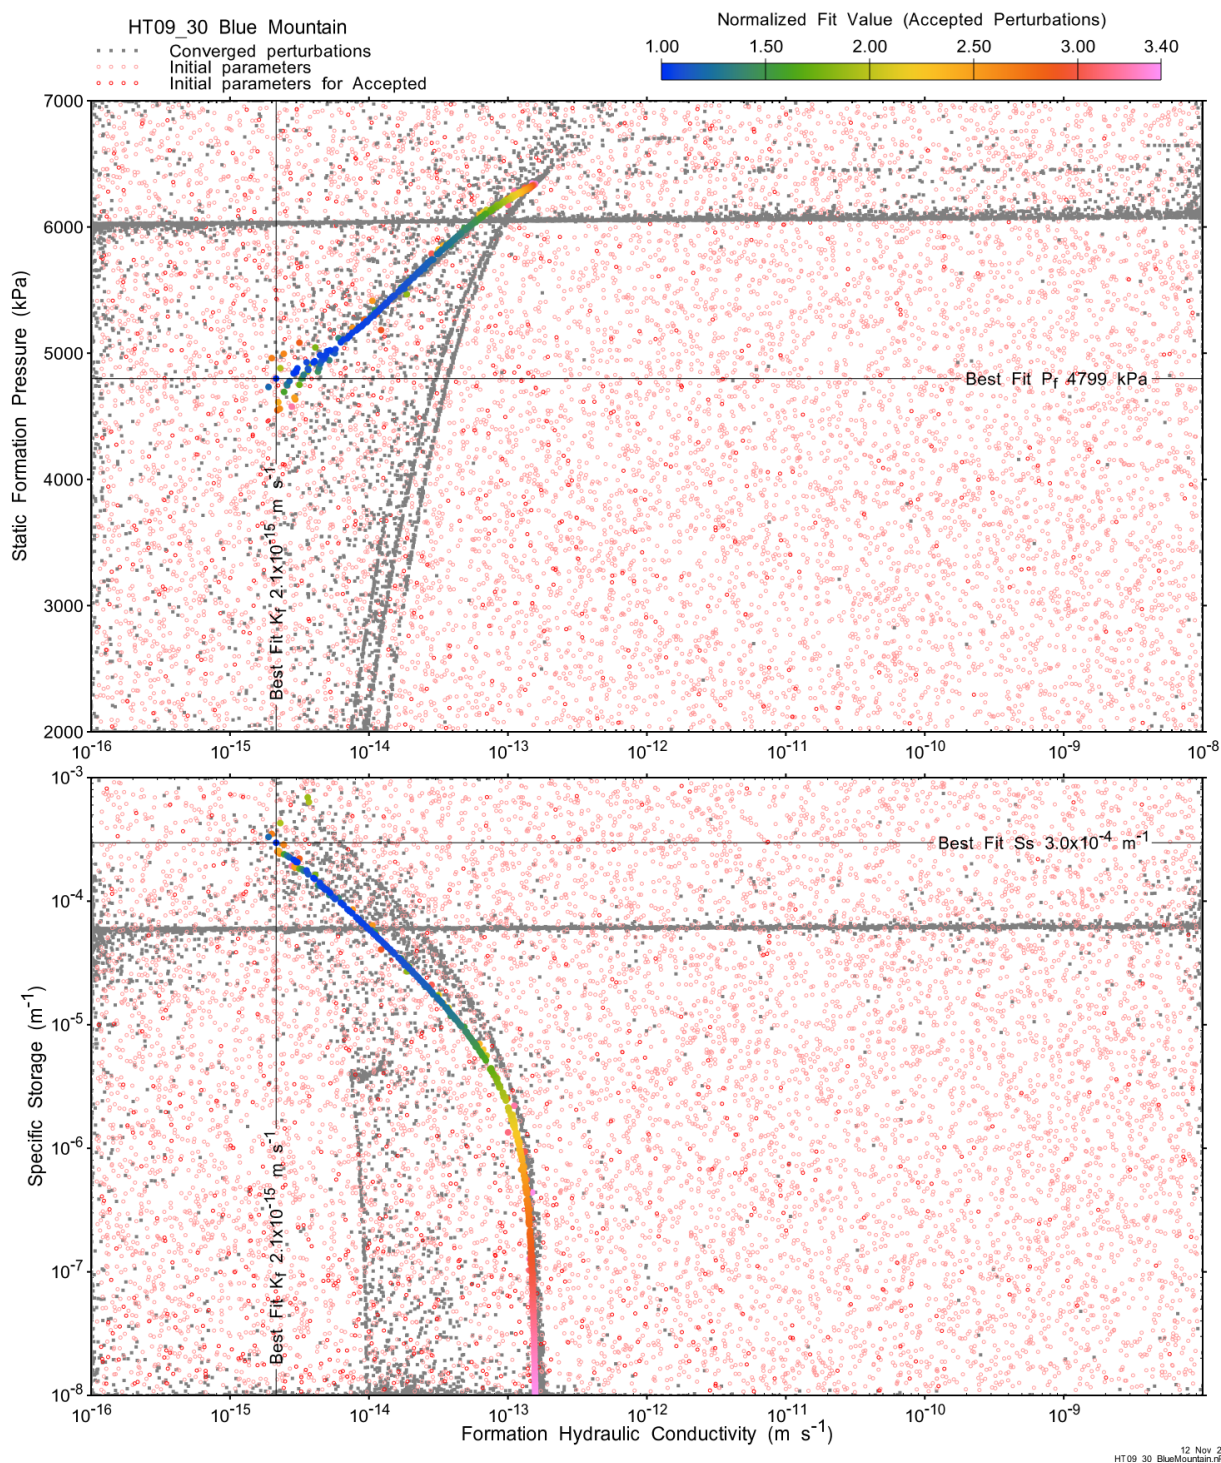

Figure A.214 - XY-scatter plot showing estimates of formation hydraulic conductivity (K_f) vs static formation pressure (P_f) (top panel) and specific storage (S_s) (bottom panel).

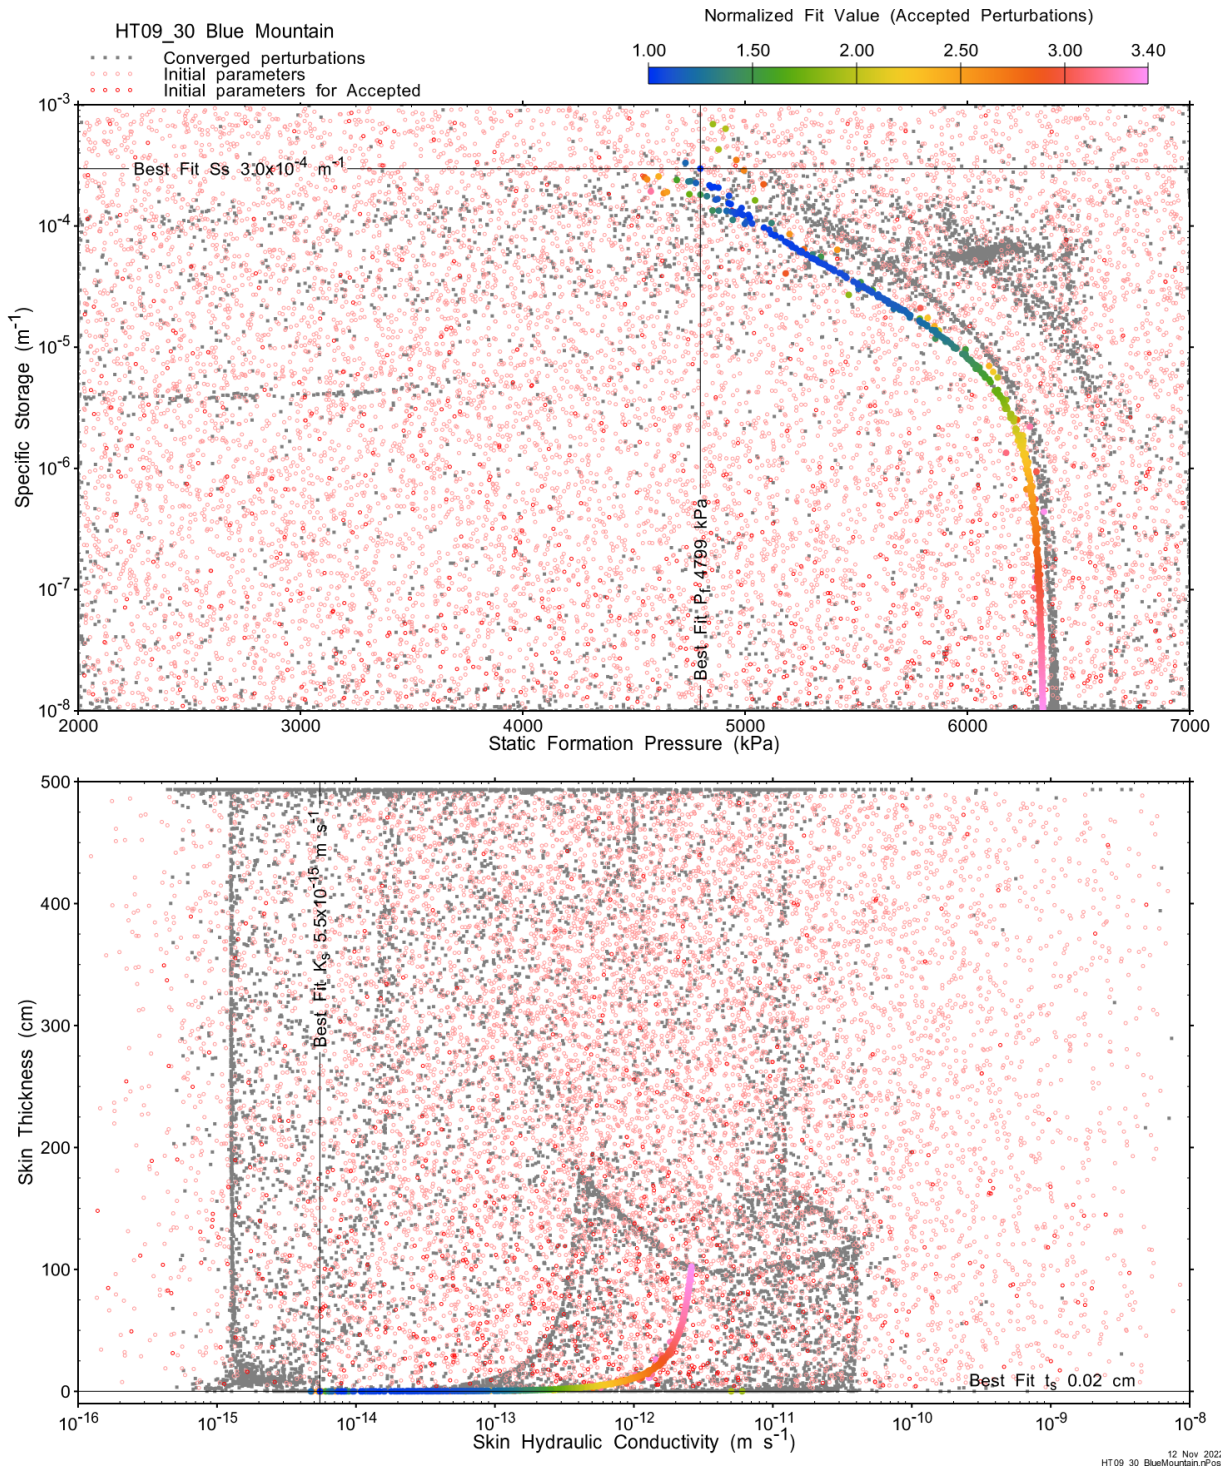

Figure A.215 - XY-scatter plot showing estimates of static formation pressure (P_i) vs specific storage (S_s) (top panel) and skin hydraulic conductivity (K_s) vs skin thickness (t_s) (bottom panel).

Confidence limits and median values are determined from the CDF of accepted optimization results (i.e. the varying color values in the above figures), with best fit value, 5% and 95% confidence indicated on Figure A.26 and Figure A.27.

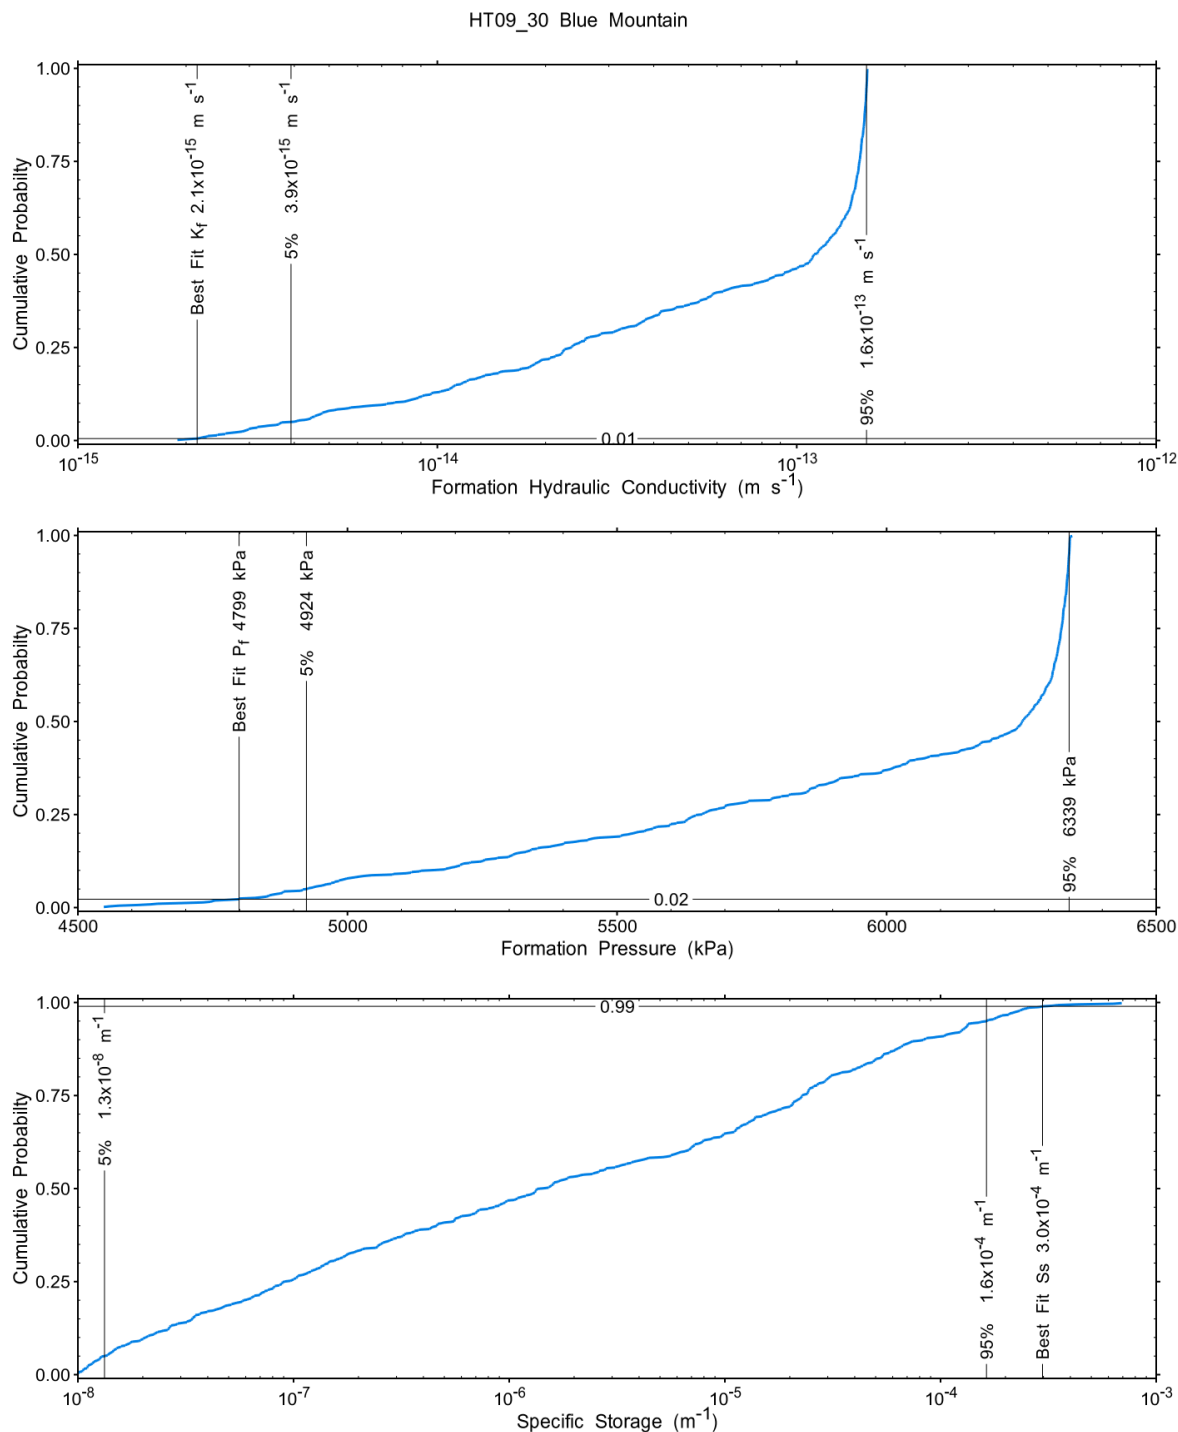

Figure A.216 – Cumulative distribution functions and parameter limits for formation hydraulic conductivity (K_f) (top panel), static formation pressure (P_f) (middle panel) and specific storage (S_s) (bottom panel).

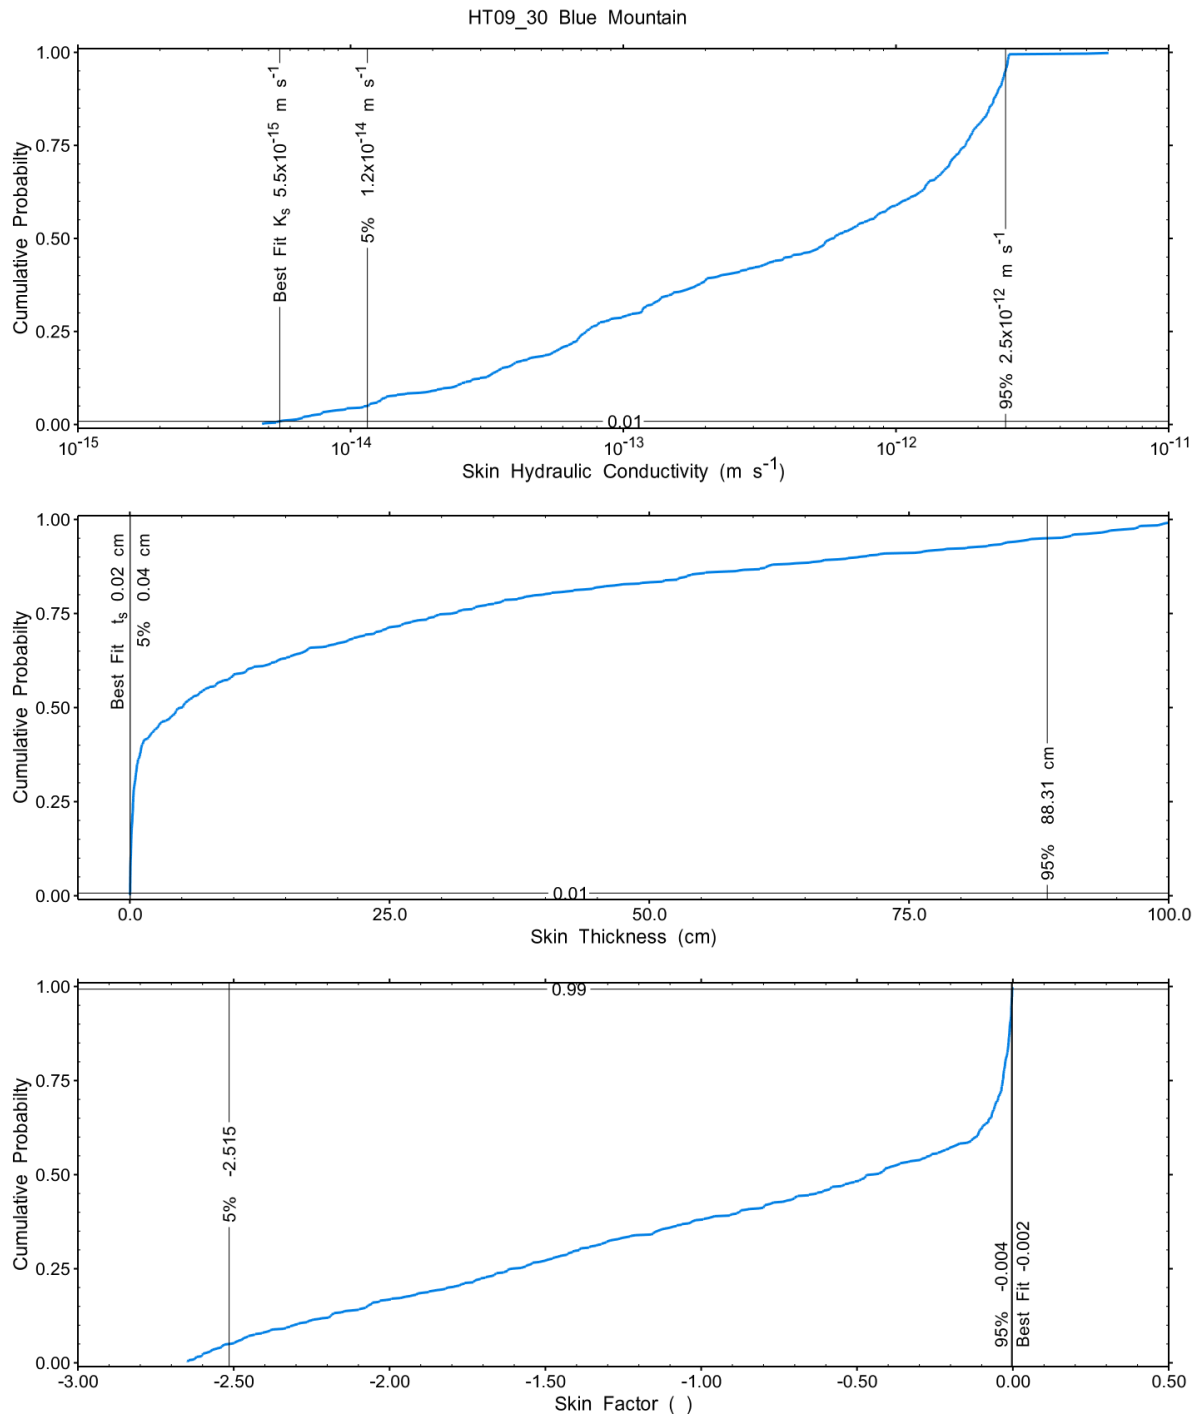

Figure A.217 – Cumulative distribution functions and parameter limits for skin hydraulic conductivity (K_s) (top panel), skin thickness (t_s) (middle panel) and skin factor (s) (bottom panel).

A summary of perturbation results is presented in Figure A.28, with Ramey-processed perturbations in Figure A.219. Those perturbations (508 of 10,000) with all parameters within the 5% and 95% range present a good fit to the measured test zone data.

Figure A.218 – Perturbation results – all converged, accepted, and within 5% to 95% for all parameters.

Figure A.219 – Log-log plot showing Ramey B and derivative response for all converged optimizations and those within 5% to 95% for all parameters.

A summary of best-fit and parameter ranges is given in Table A.9.

Table A.69 - Summary of the HT09_30 parameter estimates.

Parameter	Best Fit	5%	Median	95%
K_f (m/s)	2.1E-15	3.9E-15	1.1E-13	1.6E-13
P_f (kPa)	4799	4924	6252	6339

A.15 HT10_30 Collingwood/Cobourg

The SB BH02 interval from 671.00 to 700.96 mBGS tested in HT10_30 covers nearly the entirety of the Collingwood formation (6.54 m of 7.85 m) and the upper 60% of the Cobourg Formation (23.39 m of 38.83 m). A single PI test of two days duration was conducted.

The response for this test indicated extremely low permeability with virtually no recovery. The analyses presented below confirms this assessment but indicates an anomalously high formation pressure. We believe that this pressure is incorrect and in fact indicates equipment effects that are apparent due to the extremely low conductivity. For this reason, we believe results from this test should be qualified. A formation hydraulic conductivity of less than 10^{-15} m/s is a reasonable assumption, but other analyses values, in particular formation pressure should not be used/reported.

A.15.1 Test Data Summary

Table A.6 and Figure A.1 provide a summary of test events and a plot of pressures measured while testing respectively.

Table A.71 - Summary of Test Events.

Event	Start Date & Time	Duration (days)	TZ Pressure (kPa)
Drilling intercept	22-03-13 12:10	144.06	7114
Shut-in	22-08-04 13:35	0.79	7120
Pulse injection	22-08-05 08:31	2.00	7875
Test end	22-08-07 08:37		7778

A.18 HT13_30 Kirkfield

The SB BH02 interval from 770.00 to 799.96 mBGS tested in HT13_30 covers the majority of the Kirkfield Formation. A single PI test of two days duration was conducted.

A.18.1 Test Data Summary

Table A.6 and Figure A.1 provide a summary of test events and a plot of pressures measured while testing respectively.

Table A.86 - Summary of Test Events.

Event	Start Date & Time	Duration (days)	TZ Pressure (kPa)
Drilling intercept	22-03-18 01:14	148.53	7702
Shut-in	22-08-13 14:01	0.77	8197
Pulse injection	22-08-14 08:30	2.00	8785
Test end	22-08-16 08:36		8481

Figure A.268 - Test events and pressures.

A.18.2 Test Analyses

Table A.7 is a summary of test-specific input parameters used in the analyses, while Table A.8 presents the optimized parameters and allowed ranges.

Table A.87 – nSIGHTS Input Parameters.

Parameter	Value	Units
Test zone radius	6.37	cm
Test zone compressibility	3.91E-10	1/Pa
Test zone length	29.96	m

Table A.88 – nSIGHTS Parameter Optimization Ranges.

Parameter	Minimum	Maximum	Units	Type
Formation hydraulic conductivity (K_f)	1E-16	1E-07	m/s	log
Formation pressure (P_f)	0	10000	kPa	linear
Specific storage (S_s)	1E-08	1E-04	1/m	log
Skin hydraulic conductivity (K_s)	1E-16	1E-07	m/s	log
Skin thickness (t_s)	0.013	500	cm	linear

Figure A.18 shows the measured test zone pressure record (with reduced data density for clarity) used in the analysis along with the best-fit simulation and parameter values. Figure A.19 presents the pre-test history, and Figure A.20 shows the Ramey B normalized best-fit pressure and pressure derivatives.

Figure A.269 - Annotated testing sequence showing best-fit simulation and parameter estimates.

Figure A.270 - Annotated testing sequence showing pre-test history, best-fit simulation and parameter estimates.

Figure A.271 - Log-log plot showing Ramey B and derivative response for best-fit simulation.

Figure A.21 shows the normalized parameter sensitivity response for the best fit. Sensitivity for most fitting parameters is increasing at the end of the test, indicating that increased test duration may have yielded more precise results.

Figure A.272 - Normalized Jacobian for best-fit simulation.

A.18.3 Uncertainty Analyses

The CDF of normalized fit values for all converged simulations and the selected fit discriminant are shown in Figure A.22. Initially, the fit discriminant was set somewhat higher, but was reduced to remove local minima and to include the global minimum only.

Figure A.273 - Fit value cumulative distribution function.

Summary cross parameter scatter plots for selected formation and skin parameters are given in Figure A.24 and Figure A.25. The light pink dots on the figures are the initial parameter estimates, with red dots overlaying those initial parameter values that resulted in accepted optimization results. The grey dots are converged optimizations which did not meet the fit discriminant. Larger varying color symbols represent the fit value of accepted optimizations, with the blue values representing the best fit.
